
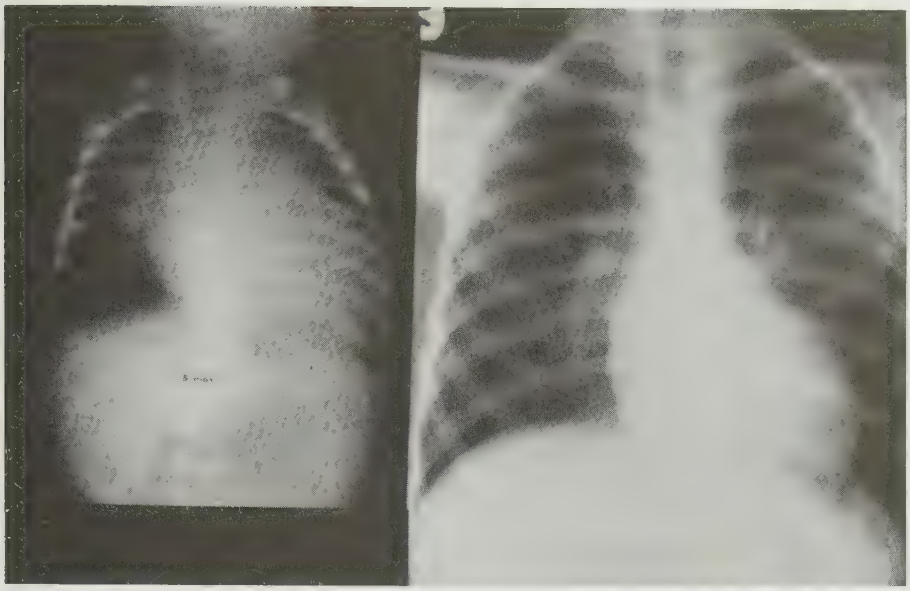

Fig. 83–5. Chest roentgenograms from patient with anomalous origin of left coronary artery from the pulmonary artery. (Left: eight months of age; right: six years of age.) Without operation, there has been spontaneous reduction of heart size and clinical improvement over 5½ years.

it is reasonable to perform an operation to establish a two-coronary artery system when ALCA is discovered. In infants (younger than one year of age) with ALCA and good left ventricular function (an ejection fraction greater than 20%), and who are doing well, it is reasonable to delay surgical correction until at least one year of age. For infants with poor left ventricular function (an ejection fraction less than 20%), it seems reasonable to intervene surgically because the natural history of the disorder in these children is poor. As surgical techniques improve and there is improvement in the survival of infants who are doing poorly (less than 1 year of age with an ejection fraction less than 20%), one might consider operating on all infants with ALCA, even those who are doing well.

At present, patients with ALCA and evidence of congestive heart failure benefit from treatment with digitalis and diuretics. Infants with evidence of acute myocardial infarction should be treated with oxygen, sedation, rest, digitalis, and diuretics.

Anomalous Origin of the Right Coronary Artery from the Pulmonary Artery

Anomalous origin of the right coronary artery from the pulmonary artery is much less frequent than ALCA.[3,26–29] The anomalous right coronary artery usually arises from the right pulmonary artery sinus and follows the distribution of a normal right coronary artery. In addition to anomalous origin of the entire right coronary artery from the pulmonary artery, branches of the right coronary artery, such as the conus artery, may arise anomalously from the pulmonary artery.

Because of the relative rarity of anomalous origin of the right coronary artery from the pulmonary artery, it is unclear whether or not it is associated with significant morbidity or mortality. Most patients are asymptomatic, but there have been several cases in which the anomaly may have been associated with cardiac arrest and death. Unlike ALCA, origin of the right coronary artery from the pulmonary artery does not cause myocardial infarction and congestive heart failure in infants and young children. A continuous or to-and-fro murmur may be a clue to the presence of this anomaly. Because of the *possible* association of anomalous origin of the right coronary artery from the pulmonary artery with sudden death, operative repair is usually recommended.[26,27]

Anomalous Origin of Both Coronary Arteries from the Pulmonary Artery

Anomalous origin of both coronary arteries from the pulmonary artery is incompatible with life unless associated anomalies exist to maintain adequate myocardial perfusion.[15,30–32] At the time of Heifetz and associates' review,[15] 25 cases of this anomaly had been reported. Seventeen of the 25 patients had additional cardiovascular anomalies, including atrial septal defect, ventricular septal defect, tetralogy of Fallot, and pulmonary atresia. All patients reported with this condition have died. Those without associated cardiac anomalies usually die within several days of birth. If anomalous origin of both coronary arteries from the pulmonary artery is associated with other cardiac malformations and its presence is apparent, surgical correction is technically feasible.

Anomalous Origin of the Left Coronary Artery from the Right Sinus of Valsalva

Anomalous origin of the left coronary artery from the right sinus of Valsalva or from the proximal right coronary artery is a rare but important malformation because it is associated with sudden death (Fig. 83–6).[33–36] After arising from the right sinus of Valsalva, the left coronary artery follows one of four routes:

1) anterior to the pulmonary artery,
2) posterior to the aorta,
3) in the ventricular septum beneath the right ventricular infundibulum,
4) between the aorta and pulmonary artery.[33]

Patients in whom the left coronary artery passes between the aorta and pulmonary artery appear to be at the greatest risk for sudden death. Sudden death is presumably due to myocardial ischemia as a result of compression of the left coronary artery between the aorta and the pulmonary artery and compromise of the lumen of the left coronary artery due to acute angulation near its origin. Cheitlin, DeCastro, and McAllister[36] reviewed 33 autopsy cases of this anomaly and found that death was sudden and un-

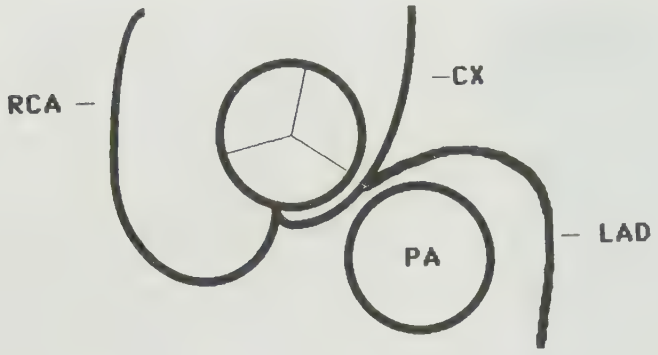

Fig. 83–6. Origin of the left coronary artery from the right aortic sinus of Valsalva. When the left coronary artery passes between the aorta and the pulmonary artery, there is risk of sudden death. CX = circumflex; LAD = left anterior descending artery; PA = pulmonary artery; RCA = right coronary artery.

expected in 27.3%.[37] Besides hypertrophic cardiomyopathy, anomalous origin of the left coronary artery from the right sinus of Valsalva is one of the more common cardiac anomalies associated with sudden unexpected death in adolescents and young adults. Unfortunately, the patients are usually asymptomatic until sudden death occurs. However, some patients may have symptoms of angina or coronary insufficiency. Symptoms may include syncope or light-headedness associated with exercise. Certainly this diagnosis must be considered in children and adolescents with angina-like chest pain, syncope, or presyncope. If this condition is suspected, exercise testing may reveal electrocardiographic evidence of ischemia, but a normal result of exercise study does not exclude the diagnosis. Coronary angiography is necessary to establish or exclude the diagnosis. However, in the future, diagnosis of this anomaly may be possible by using high-resolution echocardiography. When the left coronary artery passes between the aorta and the pulmonary artery, operative repair is indicated to prevent sudden death.

Anomalous Origin of the Right Coronary Artery from the Left Sinus of Valsalva

Anomalous origin of the right coronary artery from the left sinus of Valsalva is detected less frequently than is anomalous origin of the left coronary artery from the right sinus of Valsalva.[33,36] It may be a rarer anomaly, or it may be overlooked at the time of autopsy. If unassociated with symptoms, it may be underrepresented in coronary angiography series. Except for anecdotal cases, this anomaly is not associated with symptoms of myocardial ischemia or sudden death. Operative repair of this anomaly is indicated if signs and symptoms of myocardial ischemia are present and there are no other apparent causes for the myocardial ischemia.[3,33]

Single Coronary Artery

Single coronary artery is found in approximately 3 out of 1056 coronary angiographic studies[37,38] and 3 out of 214 patients with coronary artery anomalies.[39] It has been associated with transposition of the great arteries, coronary artery fistula, and bicuspid aortic valve. The male-to-female ratio is 1.4:1.[40] It was noted by Thebesius in 1716[41] and by Hyrtl in 1841.[42] Single coronary artery was classified by Smith[43] into three patterns: the single coronary artery predominantly followed the course of one coronary artery, either the right or left, to supply the entire myocardium; or divided to give rise to branches that distributed along normal courses of both the right and left coronary arteries; or followed a distribution that was dissimilar to the course of either the normal left or right coronary artery.

There have been three theories to explain the embryonic origin of single coronary artery: 1) congenital absence of one coronary artery anlage, 2) misplacement of one coronary artery anlage so that the misplaced anlage fused with the normally positioned anlage, and 3) abnormal closure of a coronary anlage.[44]

The clinical significance of a single coronary artery is unclear.[45–47] Kelley noted that patients in whom the single coronary artery arose from the right coronary sinus with a connecting branch that traveled between the aorta and the pulmonary artery and then distributed in the location of a normal left coronary artery were at risk for sudden death caused by the acute angulation of the connecting branch. This is similar to the situation when origin of the left coronary artery is from the right sinus of Valsalva.[48]

CORONARY ARTERY PATTERNS ASSOCIATED WITH CONGENITAL HEART DEFECTS

Tetralogy of Fallot

Although only 4 to 5% of patients with tetralogy of Fallot have associated coronary artery anomalies, it is important to recognize these abnormalities so that damage to essential coronary arteries is avoided during operative repair of tetralogy of Fallot.[49,50] Origin of the left anterior descending coronary artery from the right coronary artery occurs in 4% of patients with tetralogy of Fallot. Usually, when the left anterior descending coronary artery originates from the right coronary artery, it passes across the right ventricular outflow tract. Inadvertent division of this vessel must be avoided when right ventriculotomy is performed. Single coronary artery is the second most frequent coronary anomaly associated with tetralogy of Fallot.[50] The single coronary artery may originate from the right or left sinus of Valsalva, and the branch to the right side of the heart or the branch giving rise to the left anterior descending coronary artery and circumflex coronary artery may cross the right ventricular outflow tract and be at risk for inadvertent damage at the time of ventriculotomy. Forty percent of cases of tetralogy of Fallot have a long, large right conus artery that distributes to a significant mass of myocardium. Although this does not represent a true coronary anomaly, it is important to be aware of a large conal artery and avoid its division during repair of tetralogy of Fallot.

Additional coronary anomalies that are observed in tetralogy of Fallot include origin of the right coronary artery from the posterior sinus of Valsalva, origin of the right coronary artery from the pulmonary artery, origin of the left coronary artery from the pulmonary artery, origin of the left coronary artery from the posterior coronary sinus of Valsalva, and an accessory coronary artery originating from the posterior aortic sinus of Valsalva.[3]

Transposition of the Great Arteries

There are two major coronary artery patterns in "complete" or "simple" or "d-transposition" of the great arteries.[3,51,52] Most

commonly, the right coronary artery arises from the posterior aortic sinus, and the left coronary artery arises from the left coronary sinus and divides into a circumflex and anterior descending coronary artery (Fig. 83–7). The right aortic sinus of Valsalva is the noncoronary cusp. This pattern occurs in two thirds of cases of d-transposition of the great arteries and is most common when the aorta and pulmonary artery are obliquely oriented (aorta to the right and anterior to the pulmonary artery).

In the second coronary artery pattern, the right coronary artery arises from the posterior aortic sinus and gives rise to the circumflex coronary artery, which passes posterior to the pulmonary artery. The anterior descending coronary artery arises from the left coronary sinus, and the right aortic sinus of Valsalva is the noncoronary sinus. This pattern is present in one third of patients with d-transposition of the great arteries and is most commonly associated with great arteries that are in a side-by-side relationship.

Variations of the above pattern occur, including origin of both coronary arteries from the posterior aortic sinus; separate origin of the circumflex coronary artery from the posterior aortic sinus; dual circumflex coronary arteries arising from both the right and left coronary arteries; and dual descending coronary arteries, the second arising from a circumflex coronary artery that arises from the right coronary artery; and single coronary artery.[3]

L-Transposition of the Great Arteries

The aorta is anterior and to the left of the pulmonary artery in l-transposition of the great arteries (''corrected transposition of the great arteries'' or ''ventricular inversion''). One aortic sinus of Valsalva is oriented anteriorly (anterior sinus of Valsalva), one posteriorly and rightward (right sinus of Valsalva), and one posteriorly and leftward (left sinus of Valsalva). The right coronary artery originates from the right aortic sinus of Valsalva and divides into an anterior descending branch that follows the course of the interventricular sulcus (Fig. 83–8). The right coronary artery coninues to follow a course in the right atrioventricular sulcus. The left coronary artery originates in the left aortic sinus of Valsalva and follows the course of the circumflex coronary artery in the left atrioventricular sulcus. The left (''circumflex'') coronary artery produces a marginal branch and continues as the posterior descending coronary artery.[3]

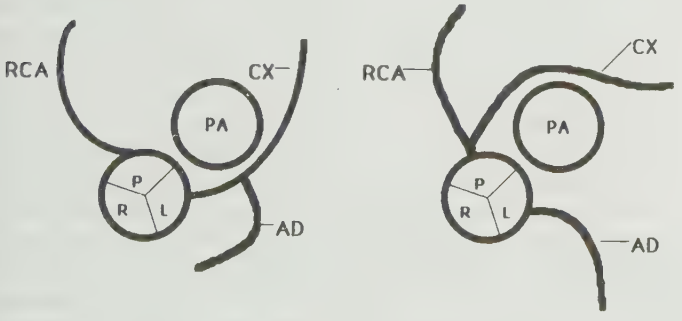

Fig. 83–7. Coronary artery patterns in d-transposition of great arteries. The pattern on the left is most commonly found when the great arteries are obliquely related. The pattern on the right is more common when great arteries are in a side-by-side relationship. CX = circumflex; AD = anterior descending artery; RCA = right coronary artery; AD = anterior coronary artery; P, R, L = posterior, right, and left aortic cusps.

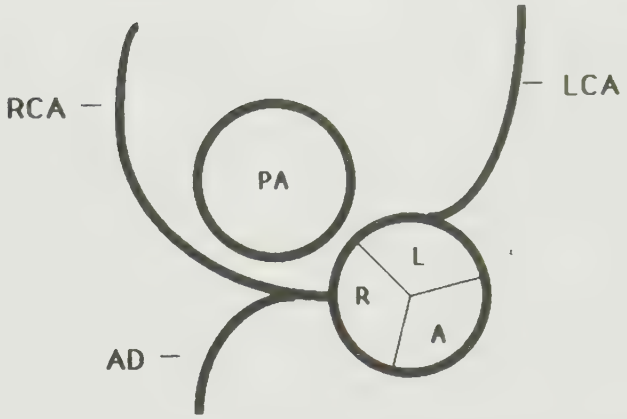

Fig. 83–8. Coronary artery pattern of l-transposition of the great arteries (''ventricular inversion'' or ''corrected transposition''). RCA = right coronary artery; PA = pulmonary artery; AD = anterior descending artery; LCA = left coronary artery; R, L, A = right, left anterior aortic cusps.

Double-Inlet Left Ventricle

Double-inlet left ventricle exists with a subaortic outlet chamber located either anteriorly and to the left or anteriorly and to the right. This outlet chamber is a rudimentary right ventricle that receives no atrioventricular valve and has no atrioventricular valve support apparatus. The outlet chamber communicates with the ''single'' left ventricle via a ventricular septal defect or ''bulboventricular foramen.'' The coronary artery pattern depends on the location of the outlet chamber and the spatial relationships of the aorta and pulmonary artery.[53,54]

When the outlet chamber is anterior and to the right, the aorta lies anterior and to the right of the pulmonary artery. In these instances, the right coronary cusp is the noncoronary sinus of Valsalva. The right coronary artery arises from the posterior aortic sinus of Valsalva and courses in the right atrioventricular sulcus. The left coronary artery arises from the left aortic sinus of Valsalva and gives rise to an anterior descending coronary artery that follows the interventricular sulcus and a left circumflex coronary artery that courses in the left atrioventricular groove. Lev and associates[53] and Keeton and associates[54] described slightly different coronary patterns in which the left coronary artery gave rise to a ''left delimiting'' artery (instead of a left anterior descending coronary artery), and the right coronary artery also gave rise to a ''right delimiting'' artery. These two delimiting arteries border the outlet chamber.

When the outlet chamber is anterior and to the left, the aorta is anterior and to the left of the pulmonary artery (Fig. 83–9). Elliot and associates[55] described two distinct coronary artery patterns. In both, the anterior aortic sinus of Valsalva was the noncoronary cusp. In the first pattern, the right coronary artery arose from the right aortic sinus of Valsalva and coursed in the right atrioventricular groove. The left coronary artery arose from the left aortic sinus of Valsalva and divided into an anterior descending coronary artery and a circumflex coronary artery. In the second pattern, the anterior descending coronary artery arose from the right coronary artery rather than the left coronary artery. Lev and associates[53] described two delimiting arteries that bordered the

RCA = right coronary artery; LCA = left coronary artery; PA = pulmonary artery; RDA = right delimiting artery; LDA = left delimiting artery; P, R, L = posterior, right, and left aortic cusps.

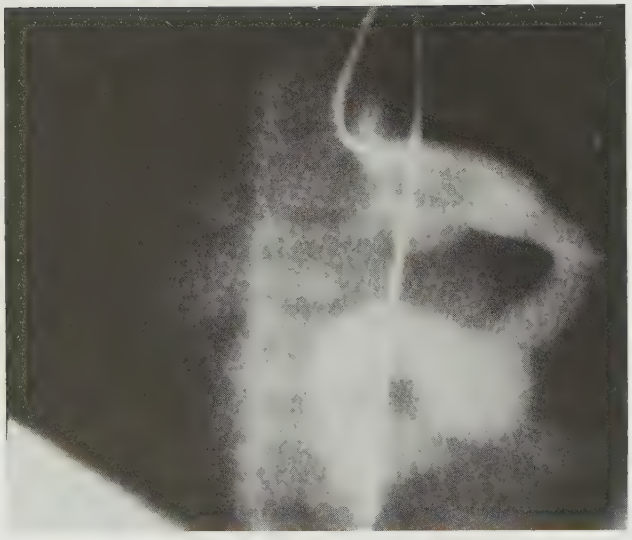

Fig. 83–10. A cineangiogram of a dilated and tortuous right coronary artery resulting from coronary artery fistula.

outlet chamber: one arising from the left and one from the right coronary artery.

Double-Outlet Right Ventricle

Usually, the coronary artery pattern in double-outlet right ventricle is normal. However, Neufeld and Schneeweiss[3] described nine separate variations of coronary anatomy in double-outlet right ventricle. Details are given in their excellent review.[3]

Truncus Arteriosus

Various coronary artery patterns occur in truncus arteriosus depending on the number of aortic valve cusps and the spatial rotation of the truncus.[3,56,57] In general, the left coronary artery arises from the left posterior cusp and the right coronary artery from the right anterior cusp. There may be a single coronary artery, or two ostia may arise in close proximity. It is important to recognize atypical coronary artery patterns and the presence of large diagonal branches of the right coronary artery that course over the entry surface of the right ventricle. These vessels are subject to injury during right ventriculotomy.

CORONARY ARTERY FISTULA

Coronary artery fistula was described by Krause in 1865[58] and Brooks in 1866.[5] Coronary artery fistula comprises 0.2 to 0.4% of congenital cardiac defects.[59] There is no apparent gender predilection. Fistulae originate equally from the right and left coronary artery systems.[3] Most commonly, the fistula connects to the right ventricular cavity via a single opening or multiple openings. The right atrium is the second most common terminus, and two thirds of those draining into the right atrium originate from the right coronary artery. A fistula can also terminate in the pulmonary artery, left atrium, left ventricle, superior vena cava, coronary sinus, or a persistent left superior vena cava. The involved coronary artery is usually dilated (Fig. 83–10), and the chamber in which the fistula terminates may be enlarged. In childhood and adolescence, the fistula usually does not produce symptoms, but signs and symptoms of congestive heart failure can occur secondary to a large left-to-right shunt. The presence of a fistula is usually detected from the presence of a continuous precordial murmur. There may be a precordial thrill, decreased diastolic blood pressure, and widened pulse pressure. The physical findings may be confused with those of patent ductus arteriosus, but the murmur of a patent ductus arteriosus is usually heard best in the left infraclavicular area and that of a coronary artery fistula at the midleft sternal border.

Angiography is necessary to confirm the diagnosis of coronary artery fistula. The differential diagnosis includes patent ductus arteriosus, the combination of ventricular septal defect and aortic insufficiency, fenestration of a coronary artery cusp, and pulmonary or chest wall arteriovenous fistulae. It is important to identify the coronary artery involved in the fistula and branches of the coronary artery in the region of the fistula for proper planning of a surgical procedure.

The presence of a coronary artery fistula is the indication for surgical obliteration of the fistula. The purpose of eliminating the malformation is to prevent eventual congestive heart failure secondary to a left-to-right shunt, rupture of the dilated coronary artery, endocarditis, and myocardial infarction or ischemia.[3]

There are several surgical procedures designed to interrupt the fistulous tracts. Depending on the particular fistula, the operation may or may not require cardiopulmonary bypass. Particular care must be taken not to interrupt important coronary artery branches when interrupting the fistulous tract.[60,61]

CHAPTER 84

Anomalies of Systemic Venous Return

James C Huhta

The variations of the normal human venous system and its development have been the object of anatomic study for many years.[1,2] Analysis of abnormalities of veins has become more relevant since the era of diagnostic cardiac catheterization and corrective cardiac surgery because patient treatment may depend in part on the details of the connection of the systemic veins. A descriptive approach to the systemic venous return can be accomplished by analyzing the veins returning to the heart, one at a time, in a segmental fashion (Fig. 84–1). These segments include the superior venae cavae, the coronary venous return, the inferior vena cava, the azygous veins, and the hepatic veins. Any scheme of description must describe the presence or absence of the segment and the connection of the segment.

Atrial situs is a key variable in the understanding of venous development. Additional discussion of situs can be found in Chapter 75. If there is lateralized situs (situs solitus or inversus), then the spectrum of abnormalities that one expects is limited and fairly predictable. The coronary sinus is usually present, and the chance of any significant abnormality is low. However, if there is abnormal situs with heterotaxy and isomeric atria, then abnormal atrial anatomy (common atrium) and the connections of venous segments are fundamentally flawed. ''Abnormalities'' are common and bizarre but predictable depending on the situs. Associations of the venous abnormalities with the various types of situs described above are summarized in Figure 84–2. One may conclude that an abnormality in situs solitus may be common with an unusual type of situs. Connection problems with the superior venae cavae, for example, are extremely rare in situs solitus but are expected in left and right atrial isomerism.[3]

EMBRYOLOGY

Paired development of the venous system is present in early stages and includes bilateral venous structures in the umbilical, vitelline, and cardinal areas. The umbilical and vitelline veins in the 13 somite stage drain bilaterally into the right and left sides of the common atrium, forming the left and right horns of the sinus venosus (the inferior wall of the common atrium). By the 20 somite stage, in situs solitus, the anterior and posterior cardinal veins (bilateral confluences called the left and right common cardinal veins) are incorporated into the respective horns of the sinus venosus (Fig. 84–3). Lateralization in venous return appears to occur by two processes: (1) invagination of the left sinus horn separating it from the left atrium and (2) rightward shift of the sinus venosus. These events lead to separation of the left horn of the sinus venosus from the developing left atrium and lateralization of all the systemic venous return to the right atrium. The hepatic veins develop from the confluence of the left and right omphalomesenteric veins, which form one confluence in the lateralization of the sinus venosus to the right. The anterior cardinal system that will drain the upper body results in the superior venae cavae, and normally, the left anterior cardinal vein regresses so that the left innominate vein (which has developed to connect the anterior cardinal veins) enlarges. The left common cardinal vein remains to drain the coronary circulation only (the coronary sinus). Obliteration of the left anterior cardinal vein results in a remnant called the ligament of Marshall and the left superior intercostal vein (dotted line in Fig. 84–3).

The embryology of the inferior vena cava (Fig. 84–4) is final-

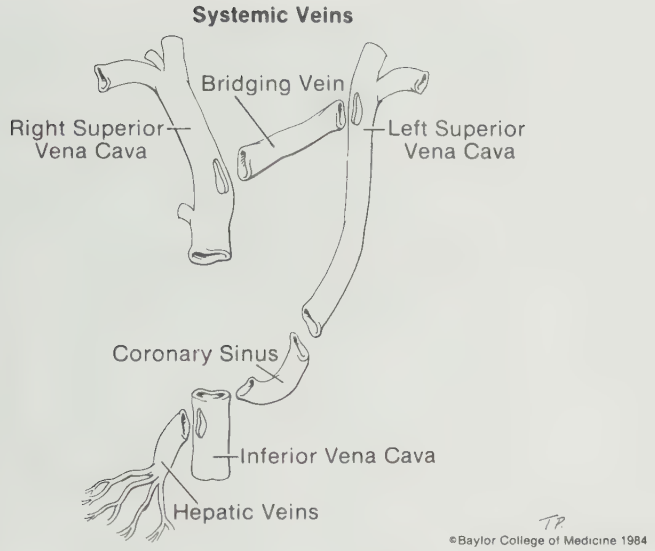

Fig. 84–1. Normal systemic venous segments. (Copyright © Baylor College of Medicine 1984. Used with permission.)

ized slightly later (between six and eight weeks of development) and forms by shifting of the venous return from the bilateral posterior cardinal system to a central confluence of veins (the inferior vena cava). The posterior cardinal system drains the caudal portion of the body, and flow transfers to the subcardinal and supracardinal veins. The posterior cardinal system of veins below the diaphragm regresses completely, and anastomoses develop between the subcardinal (ventral) and supracardinal (dorsal) bilateral systems. The subcardinal system results in the inferior vena cava from the renals to the hepatics. The supracardinal system results in the inferior vena cava below the renals and the azygous and hemiazygous veins. Right-sided dominance develops from the junction of the right subcardinal and the hepatic veins and the coalescence of the above structures.

If there are bilateral isomeric atria, then the embryologic development of the venous system is altered and cannot be compared to normal development. As a consequence of the increasing body of knowledge about the spectrum of abnormalities of abdominal situs associated with atrial isomerism, the abnormalities of venous return may be only one relatively minor part of anatomy that does not reflect "normal" development in any predictable way. There is a trend toward persistence of the bilateral nature of the venous return that is present much earlier in development. Whether the regularity of venous anomalies in atrial isomerism is due to local effects after differentiation or to a very early genetic signal is not known.

SUPERIOR VENAE CAVAE

The right superior vena cava is a derivative of the cardinal venous system and drains blood from the upper half of the body (Table 84–1). This structure is formed by the junction of the two brachiocephalic veins and is without valves. It receives the azygous vein and several small veins from the pericardium and other mediastinal structures. The lower half is within the pericardium and is covered in front and on each side by the serous pericardium.

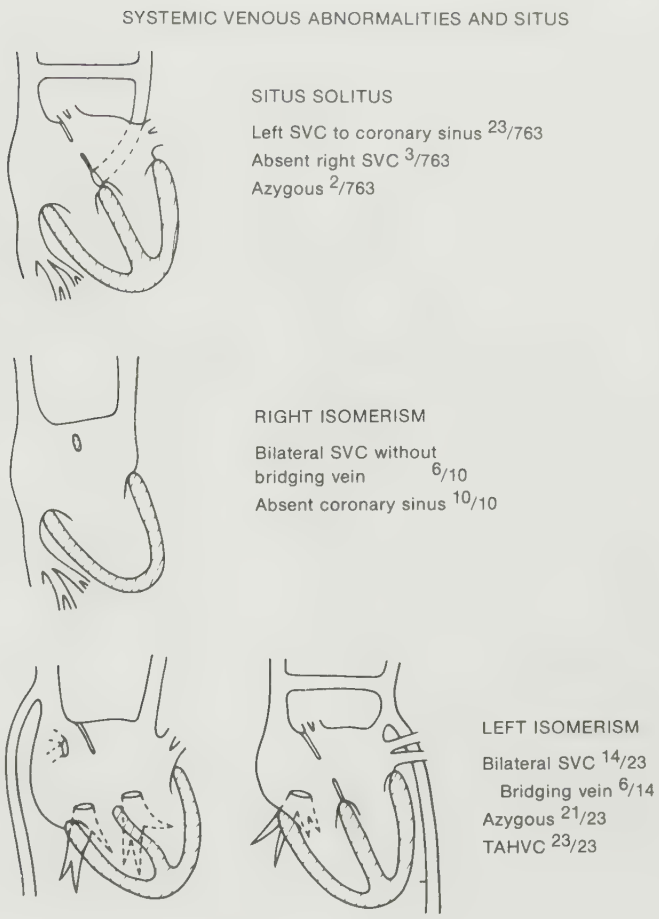

Fig. 84–2. Systemic venous abnormalities and atrial arrangement. The most common venous abnormality in situs solitus is a persistent left superior vena cava (SVC) connecting to the coronary sinus (upper panel). In right atrial isomerism, there are usually bilateral superior cavae, without a bridging vein, connecting with bilateral morphological right atria. The coronary sinus is always absent (middle panel). In left atrial isomerism, many abnormalities coexist, but all have total anomalous hepatic venous connection (TAHVC). There may be bilateral superior cavae connecting to bilateral morphological left atria, or the left SVC may connect to a coronary sinus if present. Azygous continuation of the inferior vena cava is common (lower panel). In situs inversus, the systemic venous return is a mirror image of normal. (From Huhta, J.C., et al.: Cross-sectional echocardiographic diagnosis of systemic venous return. Br. Heart J., *48*:388, 1982.)

Table 84–1. Embryologic Origin of the Major Systemic Veins

Venous Segment	*Embryologic Precursor*
Right superior vena cava	right anterior cardinal
Left superior vena cava	left anterior cardinal
Innominate vein	precardinal anastomosis
Coronary sinus	left common cardinal
Hepatic veins	omphalomesenteric
Inferior vena cava	subcardinal above renals supracardinal below renals
Azygous veins	supracardinal

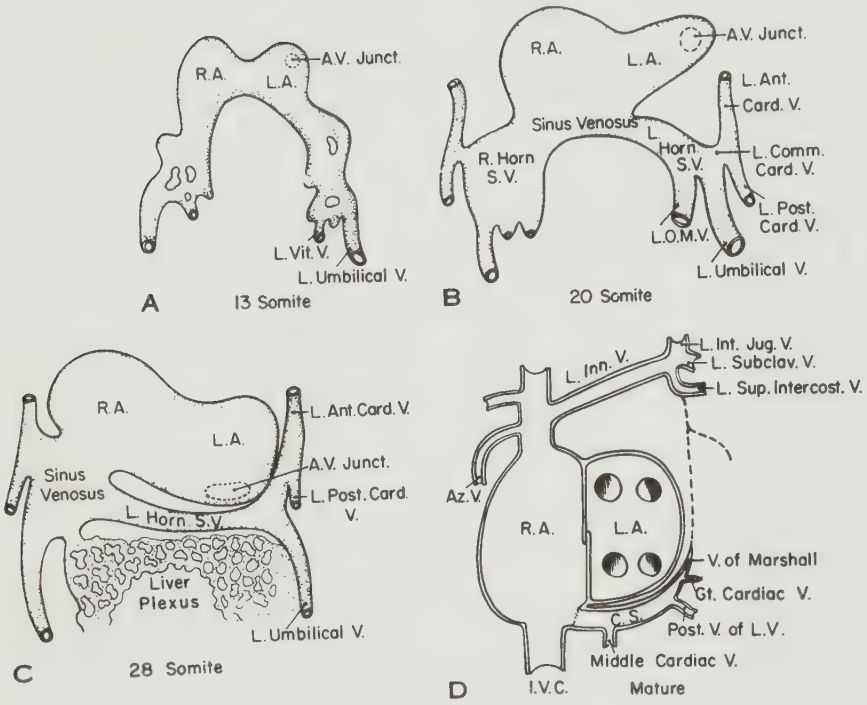

Fig. 84–3. Embryology of the cardinal venous system. (A) At 13 somite, the bilaterally symmetrical umbilical and vitelline veins drain into the right and left sides of the common atrium. (B) At 20 somite, the anterior and posterior cardinals have appeared. Asymmetrical development begins with the atrioventricular junction localized to the left side of the developing atrium and continues by the occurrence of an invagination between the left horn of the sinus venosus and the left atrium (C) finally separating these two structures and directing all systemic venous blood into the right atrium. (D) Asymmetry is continued by the development of the left innominate vein (L. Inn. V.). The common cardinal vein persists, becoming the coronary sinus (C.S.) after the left anterior cardinal vein (L. Ant. Card. V.) becomes atretic. L. Ant. Card. V. = left anterior carotid vein; L. Post. Card. V. = left posterior carotid vein; L. Comm. Card. V. = left common carotid vein; L. Umbilical V. = left umbilical vein; R.A. = right atrium; L.A. = left atrium; L. Int. Jug. V. = left internal jugular vein; L. Subclav. V. = left subclavian vein; L. Sup. Intercost. V. = left superior intercostal vein; V. of Marshall = Marshall's vein; Gt. Cardiac V. = great cardiac vein; Post. V. of L.V. = posterior vein of the left ventricle; Middle Cardiac V. = middle cardiac vein; I.V.C. = interior vena cava; Az.V. = azygous vein; L.Vit. V. = left vitelline vein; R. Horn S.V. and L. Horn S.V. = right and left horn of the sinus venosus; A.V. Junct. = atrioventricular junction; L.O.M.V. = left omphalomesenteric vein. (From Lucas, R.V., Jr., and Schmidt, R.E.: Anomalous venous connections, pulmonary and systemic. *In* Heart Disease in Infants, Children, and Adolescents. 2nd Ed. Edited by A.J. Moss, F. Adams, and G.Z. Emmanouilides. Baltimore, Williams & Wilkins, 1977.)

The shadow of its lateral border can be seen in routine chest roentgenograms.

Persistent Left Superior Vena Cava

A persistent left superior vena cava may drain via the coronary sinus to the right atrium or may drain abnormally to the left atrium, either directly with absence or unroofing of the coronary sinus or to a left pulmonary vein (partially persistent left superior vena cava). A right superior vena cava is present and may or may not communicate with the left superior vena cava. Bilateral superior venae cavae (double venae cavae) have been known to occur approximately once in every 348 autopsies[4] (Fig. 84–5). The innominate vein may be absent, small, or well developed. In general, the size of the innominate vein is inversely proportional to the size of the persistent left vena cava.[5,6] The course of a persistent left superior vena cava may be anterior to (Fig. 84–6) or posterior to the left pulmonary artery. The potential for obstruction exists in the latter case. A left superior vena cava may occur without a right superior vena cava,[7,8] in which case all the superior caval venous return drains to a greatly enlarged coronary sinus via the persistent left cava. In congenital heart disease (presumably with situs solitus), a persistent left superior vena cava was associated with tetralogy of Fallot in 20% of cases and Eisenmenger's syndrome in 8% of cases.[9]

Diagnosis of left superior vena cava may be indicated on chest roentgenogram by a shadow along the left medial border of the mediastinum. It may be suspected on clinical examination by abnormal jugular pulses.[10] Frequently, a left superior P wave axis is associated with a persistent left superior vena cava;[11] however, this is a common finding in left atrial isomerism. Echocardiography will demonstrate an enlarged coronary sinus and the anomalous vein can be detected with a sensitivity of 95 to 100%[3] (Table 84–2).

Left Superior Vena Cava Connecting to the Left Atrium

In this anomaly, the persistent left superior vena cava passes anterior to the left pulmonary artery and connects directly to the left atrium immediately below the atrial appendage and anterosuperior to the left upper pulmonary vein[12,13] (Fig. 84–7). This is most commonly associated with bilateral left or right atria. Particularly with right atrial isomerism, the coronary sinus is absent. Although this anomaly can be explained by failure of development of the coronary sinus, this explanation may not be relevant in the presence of atrial isomerism. Rarely, this defect may occur with

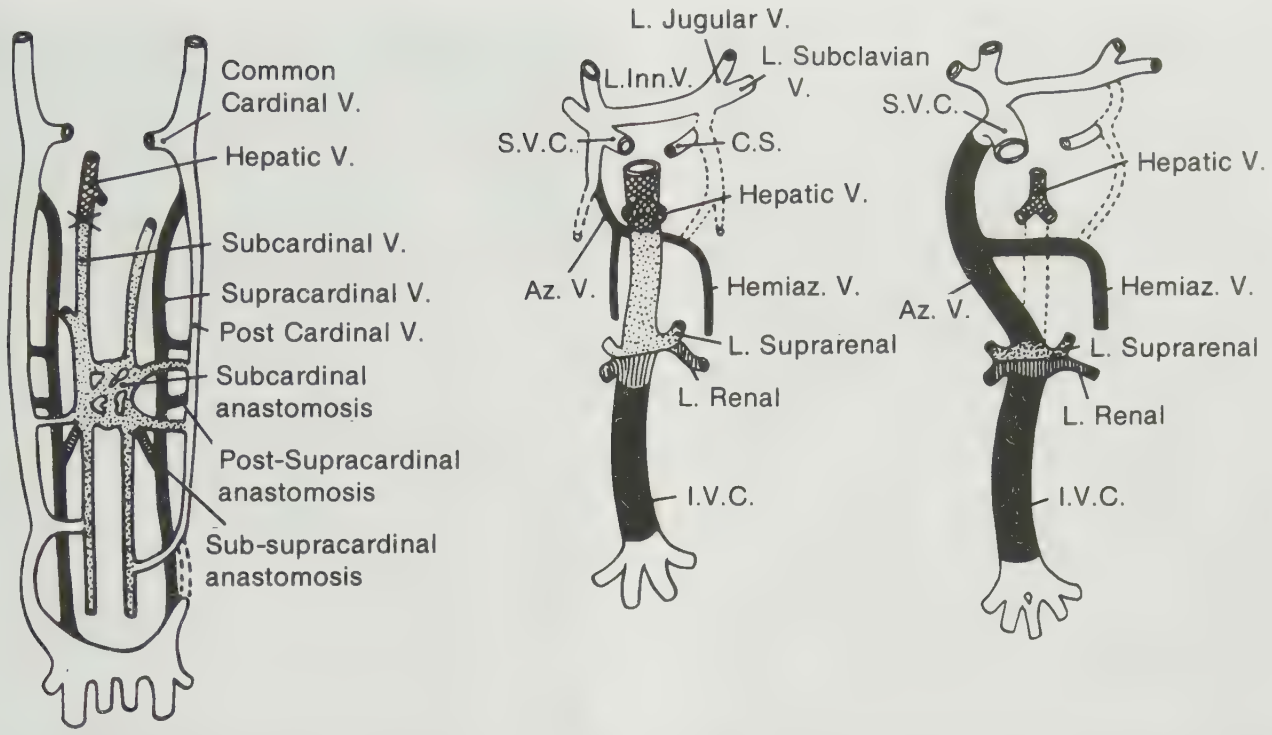

Fig. 84–4. Embryologic development of the inferior vena cava (IVC). (Left) Early stage. Venous blood from the lower body may reach the heart by way of the posterior cardinal veins (Post. Cardinal V.), the supracardinal veins, and the upper portion of the IVC, derived from hepatic and subcardinal veins. Multiple anastomotic sites between these venous systems exist in the renal area as shown. (Center) Normal development of IVC. The major venous drainage channel from the lower body is by way of the IVC, derived, from below upward, from the posterior cardinal system (white), the supracardinal system (black), the renal collar (lines), the subcardinal system (stippled), and the hepatic veins (cross-hatched). A small accessory venous channel is provided by persistence of the supracardinal veins, as hemiazygous and azygous veins. (Right) Interruption of the IVC with azygous continuation. Failure of junction of the right subcardinal vein and hepatic vein occurs and results in absence of the IVC from the region of the renal veins upward. The hepatic veins drain directly into the right atrium. All other blood from the lower body drains normally to the junction of the renal veins with the IVC and then continues by way of a greatly dilated azygous vein into the superior vena cava. L. = left; V. = vein; Inn = innominate; AZ. = azygous; SVC = superior vena cava; C.S. = coronary sinus; Hemiaz. = hemiazygous. (From Lucas, R.V., Jr., and Schmidt, R.E.: Anomalous venous connections, pulmonary and systemic. *In* Heart Disease in Infants, Children, and Adolescents. 2nd Ed. Edited by A.J. Moss, F. Adams, and G.Z. Emmanouilides. Baltimore, Williams & Wilkins, 1977.)

extensive unroofing of the coronary sinus in situs solitus. If this occurs as an isolated defect without other interatrial communication, the presentation is cyanosis early in infancy without a heart murmur. The diagnosis can be made by angiography or echocardiographic contrast injection in the left arm (see below). Surgical treatment consists of ligation if there is a bridging innominate vein or if the upper venous pressure is less than 15 mm Hg with ligation of the anomalous vena cava. Alternatively, the left superior vena cava can be reimplanted into the right atrium[14] or the pulmonary artery.[15] Today, the favored procedure is creation of an intra-atrial baffle.[16] If a common atrium is present, the entire conduction system is to the left of the baffle. The association of left superior vena cava connecting to the left atrium was one of the early observations in the heterotaxy syndrome.[17]

Right Superior Vena Cava Connecting to the Left Atrium

This rare abnormality can cause cyanosis; it can be thought of as a form of atrial septal defect with overriding of the superior vena caval entry.[18,19] The results are hemodynamically similar to connection of a persistent left superior vena cava to the left atrium.

CORONARY SINUS

Normally, the coronary sinus is a right atrial structure and is thought to be formed by invagination of the left portion of the anterior cardinal system into the left atrium. Mantini and associates summarized the rare types of coronary sinus anomalies encountered at autopsy.[20] Absence of the coronary sinus is common in atrial situs abnormalities with atrial isomerism and is distinctly uncommon with lateralized situs.[3] Atresia of the coronary sinus orifice is extremely rare[21,22] but is very important because of the possibility that ligation of a persistent left superior vena cava that drains the coronary veins could cause severe myocardial ischemia. If stenosis or atresia of the coronary sinus occurs, then the thebesian veins may provide adequate drainage of myocardial venous blood to the right atrium. Unroofed coronary sinus is a defect in the superior aspect of coronary sinus as it passes behind the left atrium, thereby creating an entry for desaturated blood into the left atrium. This defect may be associated with atrial septal defect or may occur in isolation and presents in a manner that is similar to left superior vena cava connection to the left atrium. The diagnosis can be made by contrast echocardiography (Fig. 84–8).

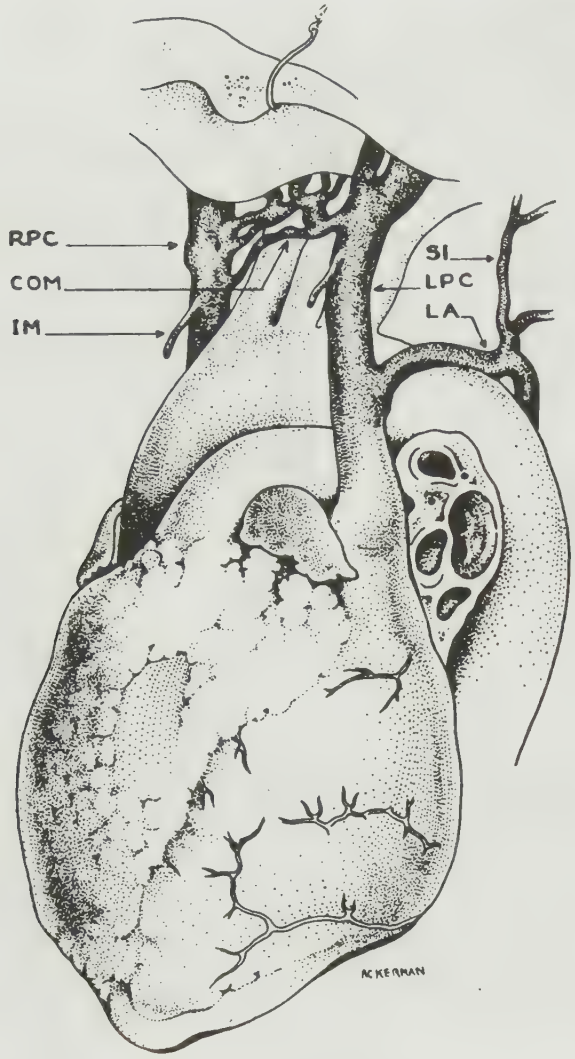

Fig. 84–5. Bilateral superior vena cavae. Left lateral view of the heart showing precavae and small cross-connection (bridging vein). COM = bridging innominate vein; IM = internal mammary; LA = left azygous; LPC = left precava; RPC = right precava; SI = superior intercostal vein. (Sanders, J.M.: Bilateral superior vena cava. Anat. Rec., *94*:657, 1946.)

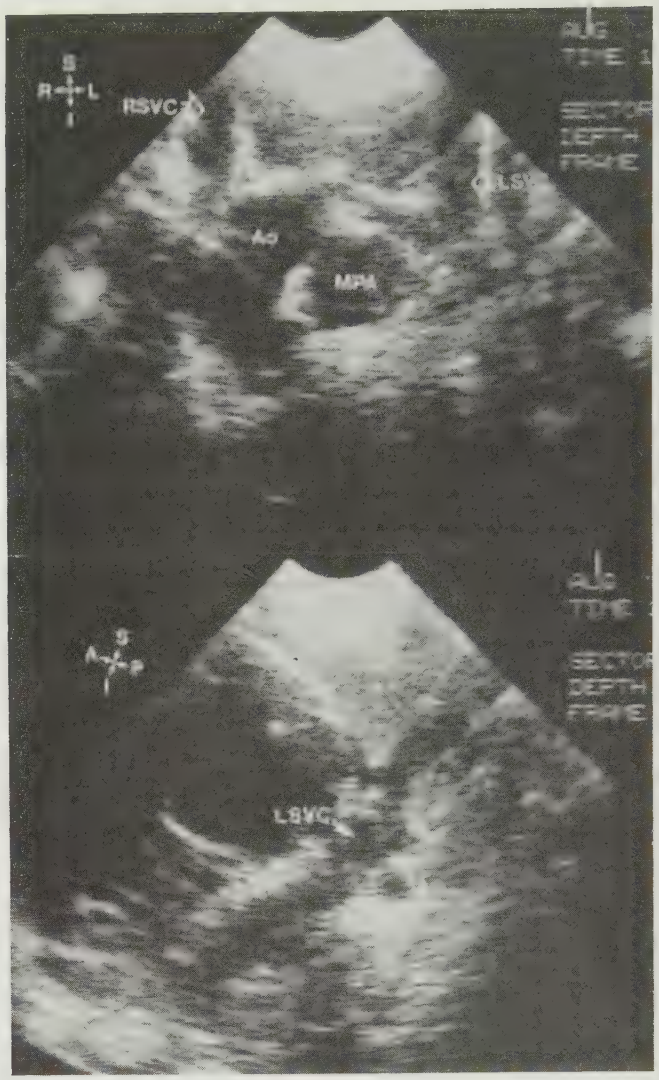

Fig. 84–6. Bilateral superior vena cavae with no bridging vein connecting them. Suprasternal scans by echocardiography show the right and left superior cavae (RSVC and LSVC) and the course of the left cava anterior to the left pulmonary artery (open arrow in the lower panel). A = anterior; Ao = aorta; I = inferior; L = left; MPA = main pulmonary artery; P = posterior; R = right.

	800 Patients			
	Right SVC	*Left SVC*	*Bilateral SVC*	*Bridging Innom. Vein with Bilateral SVC*
2-D Echo: Yes	792	46	38	13
No	8	754	762	25
Angiography: Yes	792	48	40	18
No	8	752	760	20
Sensitivity	100%	96%	95%	72%
Specificity	100%	100%	100%	100%

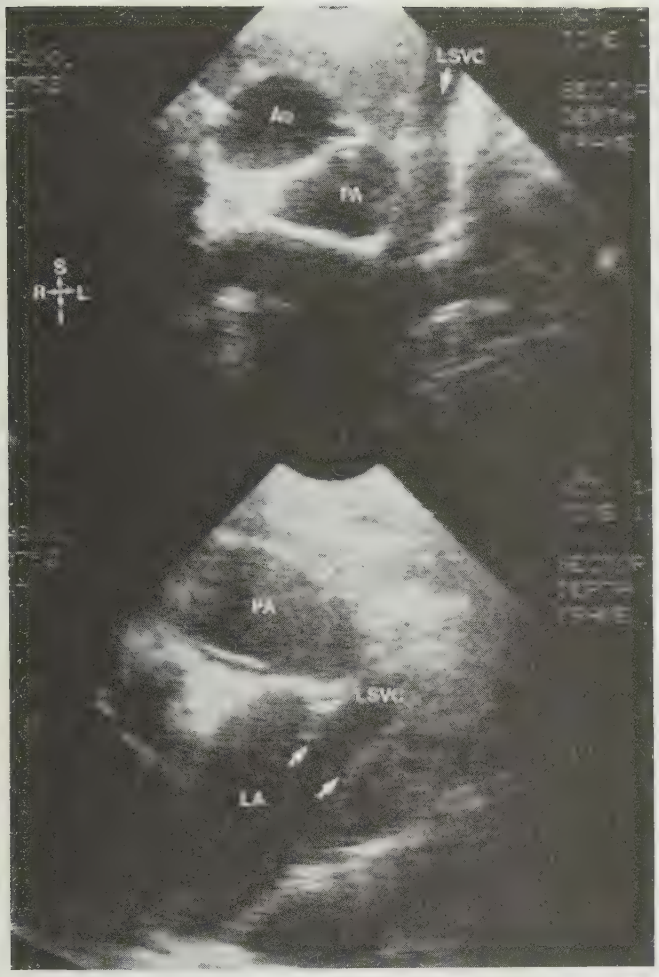

Fig. 84–7. Left superior vena cava (LSVC) connecting to the left atrium (LA) directly in a patient with left atrial isomerism. The LSVC passes anterior to the pulmonary artery. A = anterior; Ao = aorta; I = inferior; L = left; MPA = main pulmonary artery; P = posterior; R = right.

An atrial septal defect of the coronary sinus type is rare but is distinguished from a primum defect by the absence of a normal coronary sinus in the former. Rarely, the coronary sinus connects to the inferior vena cava instead of the right atrium.

INFERIOR VENA CAVA

There is a broad spectrum of variations in inferior caval return below the level of the renal veins. However, the position of the inferior vena cava superior to the renal veins is relatively constant, passing anteriorly as it ascends. Although embryologists have perceived that the portion of the inferior vena cava connecting to the heart was independent of the hepatic veins, there is no evidence to support this concept in humans. On the contrary, the occurrence of direct hepatic connection to the heart in left atrial isomerism argues against such a "segment" above the liver. The spectrum of inferior systemic venous return in 1000 consecutive patients seen in a pediatric cardiology clinic revealed a completely normal pattern in 97%[3] (Fig. 84–9). In the normal pattern, the vena cava

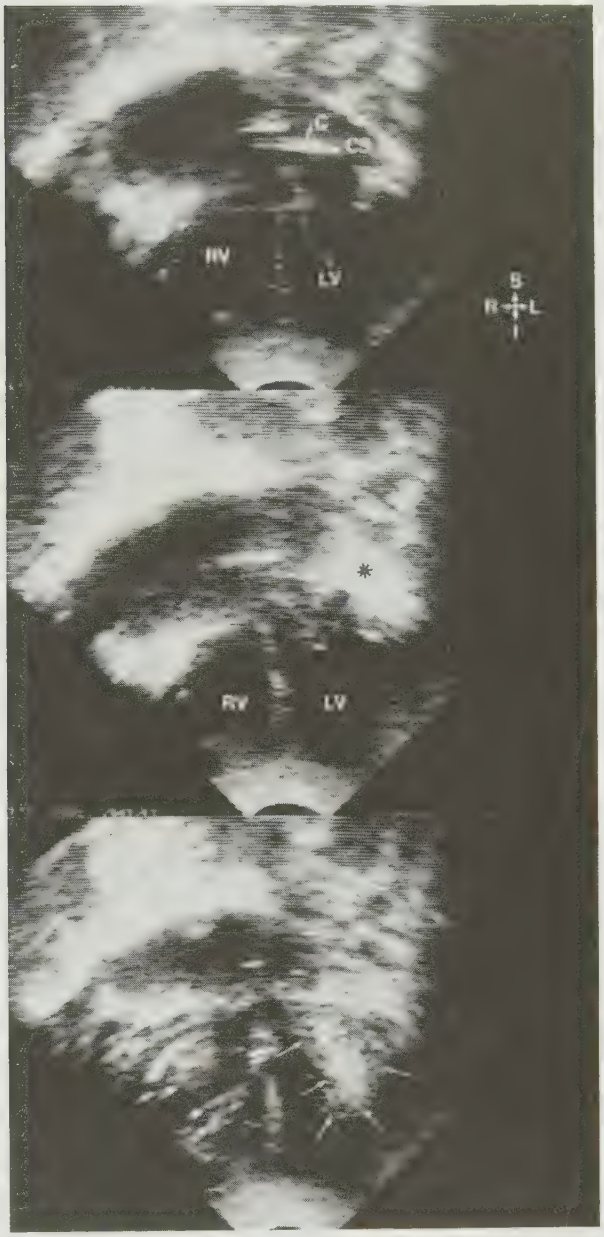

Fig. 84–8. Catheter (C) echocardiographic contrast injection in the left superior vena cava via the coronary sinus (CS) in a patient with unroofed coronary sinus. The contrast (asterisk) fills the coronary sinus in the left lateral atrioventricular groove first (middle panel), and later the mitral valve and the left ventricle (white arrows in the lower panel). I = inferior; L = left; R = right; S = superior; RV = right ventricle; LV = left ventricle.

is symmetrically placed to the right of the spine with the aorta to the left. Separate connection of the inferior vena cava without receiving hepatic venous connection was rare but occurred only in cases of left atrial isomerism. The location of the inferior vena cava is useful in the diagnosis of atrial situs by echocardiography (Fig. 84–10). Elliot and associates described the course of the inferior vena cava and the aorta together in patients with asplenia syndrome undergoing venous angiography.[23] Echocardiography is useful to image the inferior vena cava[24] and shows it to be lateral and anterior to the aorta on the same side in these patients with asplenia[25] (Fig. 84–11).

INTERRUPTION OF THE INFERIOR VENA CAVA WITH AZYGOUS CONTINUATION

Azygous and Hemiazygous Veins

Formed from paravertebral drainage of the right ascending lumbar vein, subcostal vein, and lumbar azygous vein (if present), the common azygous trunk ascends in the posterior mediastinum to the level of the fourth thoracic vertebra, where it arches forward above the root of the right lung and ends in the superior vena cava, just before that vessel pierces the pericardium. At this site, the azygous vein is joined by the confluence of the second, third, and fourth posterior intercostal veins, which is called the right superior intercostal vein.

The hemiazygous vein arises on the left similarly to the azygous vein and ascends adjacent to the vertebrae, draining the left renal vein, lumbar azygous vein, lumbar veins, and lower three posterior intercostal veins. It crosses the midline across the anterior surface of the eighth vertebral body and connects to the azygous vein on the right.

Interruption of the inferior vena cava with azygous continuation is usually present in patients with left atrial isomerism but may occur in situs solitus with a small remnant of inferior vena cava.[3] With congenital heart disease, the prevalence is approximately 0.6%.[26] Both the azygous and hemiazygous veins may be patent with azygous continuation.[3,27–29] Azygous continuation of the inferior vena cava has importance for patient care because cardiac catheterization may be more difficult in these patients. Patients with left atrial isomerism are prone to this anomaly and also prone

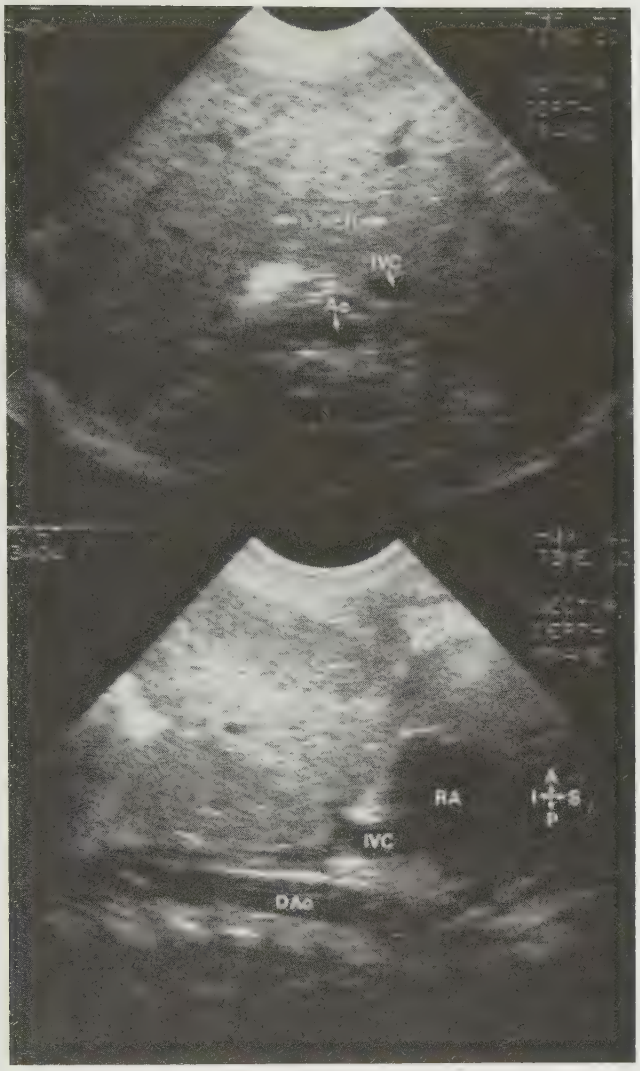

Fig. 84–11. Abnormal position of the inferior vena cava on the left in a patient with right atrial isomerism. Note that the aorta (Ao) and the inferior vena cava (IVC) run together. RA = right atrium; DAo = descending aorta.

to complete AV block. Such a patient may need an emergency pacemaker, which can be difficult to place via an azygous vein.

Hepatic Veins

Both hepatic lobes normally drain directly to the inferior vena cava. Partial and total anomalous connection refers to connection elsewhere of part or all of the hepatic veins. Partial hepatic connection directly to the heart is most common in right atrial isomerism but may occur in situs solitus or situs inversus.[3] Another reported site of partial anomalous connection is to the coronary sinus. Total anomalous hepatic venous connection occurs in left atrial isomerism, and the veins may connect to the heart via one trunk (most common) or two trunks. Anomalies of the hepatic veins can be diagnosed easily by echocardiography and may be important to identify before the correction of congenital heart defects or before liver transplantation.

MULTIPLE ANOMALIES

Complexes with multiple anomalies of systemic venous connection are almost invariably associated with abnormal atrial situs and atrioventricular septal defect (AV canal).[30–33] It is useful to screen for splenic presence by a blood smear for Howell-Jolly bodies in older infants and children with complex defects. The presence of abnormal stomach position, a midline liver, dextrocardia, azygous continuation of the inferior vena cava, bilateral bronchi or pulmonary arteries, or any abnormal venous connection other than a persistent left superior vena cava to the coronary sinus should raise suspicions of abnormal situs.

THE FUTURE: NEWER DIAGNOSTIC TECHNIQUES

Radionuclide studies can be used to detect abnormal shunting of blood into the left atrium. For example, left arm tracer injection will reveal early appearance of tracer in the left atrium in a patient with abnormal connection of a persistent left superior vena cava to the left atrium.[38,39] Nuclear magnetic resonance imaging techniques are proving to be sensitive in the diagnosis of venous abnormalities, especially with rapid acquisition flow display. Computed tomography may be useful in detecting abnormal thoracic venous structures.[40]

SURGICAL SIGNIFICANCE

The surgical significance of systemic venous anomalies lies in the need to plan for bypass cannulation technique[34] and to correct complex congenital heart defects. If systemic and pulmonary venous connections are near one another, then some type of baffle procedure may be necessary. If the operation is a type that is a variation of the Fontan procedure, then the ipsilateral superior vena cava and pulmonary artery may be connected with ligation of the superior vena cava as it meets the right atrium. Azygous continuation of the inferior vena cava will require a larger size of cannula at its site of connection because it is returning all of the inferior venous flow to the heart. Unroofed coronary sinus may be closed with a patch directly via the atrial septum or a left atrial incision.[35]

NONSURGICAL TREATMENT

If there is doubt about whether a persistent left superior vena cava can be ligated, then temporary balloon occlusion to the vein while measuring proximal pressure at catheterization can be used to test the outcome.[36] Obstruction of a superior vena cava after surgical repair of transposition of the great arteries has been successfully treated with balloon angioplasty at the time of cardiac catheterization.[3]

CHAPTER 85

Arteriovenous Fistulae

L Paul Gerson

HISTORY

Perhaps the earliest report of an arteriovenous fistula was made by William Hunter in 1757.[1] In his paper, Hunter described a thrill and a bruit over the lesion and noted the presence of an enlarged artery proximal to the fistula. He pointed out that the thrill and bruit could be eliminated by exerting pressure over the feeding artery.

Sir Prescott Hewett in 1867 reported a congenital arteriovenous fistula in a 17-year-old girl who was born with enlargement of the right thigh, and, as the patient stated, "a peculiar beating" in the right leg.[2] Hewett described his patient as follows: "The right lower extremity was found to be much enlarged, being not only increased in circumference, but at least two inches longer than the left. The superficial veins were much dilated and stood out in the form of large, convoluted and tortuous cords under the skin. The femoral vein could also be felt to be much enlarged in the groin and in it could be perceived a distinct vibratory thrill. A very loud continuous blowing sound could be traced up the vein to the same spot."[2]

Reports of arteriovenous fistulae described the effects of these fistulae on heart size, blood pressure, skin temperature, and limb growth.[3–8] As these papers were published, a confusing array of names and descriptive terms for arteriovenous fistulae was compiled. At the same time, numerous syndromes were named that contained as part of their stigmata some sort of vascular malformation (Table 85–1).

In time, as the embryology of the vascular system was better understood, a unifying embryologic etiology for congenital vascular malformations was realized.[9–13] This concept has helped to replace the myriad of old terms with a more concise classification of arteriovenous fistulae. One special case—the coronary arteriovenous fistula—is discussed in Chapter 83 rather than here.

EMBRYOLOGY

The vascular system first appears within the primitive mesenchyme as undifferentiated blood containing spaces. These spaces coalesce, disappear by absorption, and separate from one another to form discrete channels that ultimately come to be the capillary

Table 85–1. Synonyms for Arteriovenous Fistula and Angioma Syndromes

Table 85–2. Classification of Arteriovenous Fistulae

Designation	*Embryonic Stage at Time of Development*
Hemangioma	Capillary network stage
Microfistulous arteriovenous fistula	Retiform stage
Macrofistulous arteriovenous fistula	Retiform stage
Anomalous mature vascular channels	Stage of gross differentiation (arterial stem formation)

(From Szilagyi, D.E., Elliott, J.P., DeRusso, F.J., and Smith, R.F.: Peripheral congenital arteriovenous fistulas. Surgery, *57*:61, 1965.)

bed. Continued differentiation of the vascular bed results in the creation of separate venous and arterial conduits on either side of the capillaries. Arterial stems then make their way into the evolving vascular tree.

Woolard[14] has described this sequence of events as 1) the stage of undifferentiated capillary network, 2) the retiform stage, in which plexiform structures representing primitive arterial and venous channels evolve from the equipotential capillary bed, and 3) the stage of mature vascular stems following the disappearance of the primitive elements.

The development of the vascular system through this evolutionary process takes place from the fifth through the tenth weeks of fetal life.[15] Errors can occur at any step along the process and, depending on when the error occurs and which area of the vascular tree is involved, result in various types of vascular malformations.

CLASSIFICATION

Szilagyi et al.[16] created a classification of four types of congenital arteriovenous fistulae and correlated each with the stage of embryonic development during which the malformation was created (Table 85–2). They specifically noted that the lesion termed hemangioma did not represent a neoplasm, and that any growth these undergo is not from cell multiplication but from hemodynamic changes. In this classification, the microfistulous lesion was one that was not readily apparent angiographically, despite the fact that abnormal arteriovenous connections were present and could be detected by other means.

Malan and Puglionisi have devised a developmental classification that is primarily morphologic in its designation of the types of arteriovenous fistulae.[15] They proposed four types of congenital malformation based on where the defect occurs within the primitive vascular tree (Fig. 85–1).

While these classifications have helped to simplify and codify our understanding of arteriovenous fistulae, it should be borne in mind that not every case fits neatly into one category or another. In addition, methods of classification that depend heavily on inference about embryologic origin of malformations may become outdated and cumbersome when new embryologic evidence becomes available (as was learned with embryologic approaches to the nomenclature of intracardiac malformations). In actual practice, one encounters lesions that show elements of more than one type of vascular malformation, and the angiographer must be able to recognize and describe these components.

In this chapter the following morphologic classifications are used in discussion of the various types of arteriovenous fistulae (see Fig. 85–1):

1. Capillary angioma
2. Macrofistulous arteriovenous fistula
3. Truncal arteriovenous fistula

Capillary Angioma

Mulliken has demonstrated that some lesions of small vascular channels show the presence of endothelial cell proliferation and increased numbers of mast cells, indicating that these lesions are actually neoplasms.[17,18] We reserve the term *hemangioma* for these tumors. Thus, the term *capillary angioma* is used to describe congenital malformations of capillaries, to avoid any sense that these lesions are neoplasms (hemangiomas).

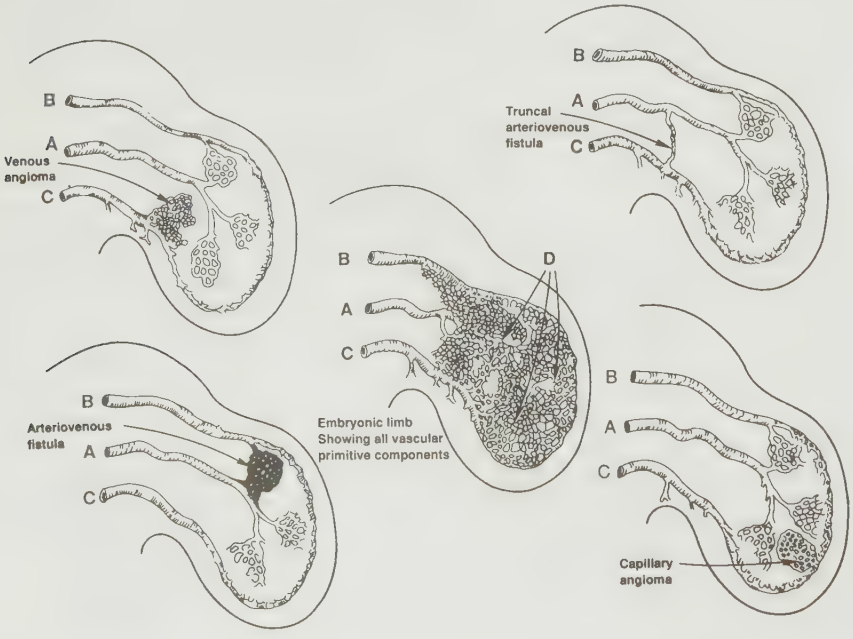

Fig. 85–1. Schematic representation of primitive vascularity and types of vascular malformations in the embryonic limb. A: axial artery; B: marginal cephalic vein; C: marginal caudal vein; D: primitive capillary network. (Adapted from Malan, E., and Puglionisi, A.: Congenital angiodysplasias of the extremities. J. Cardiovasc. Surg., 5:87, 1964.)

Capillary angiomas may be cutaneous or deep, flat or cavernous, single or multiple, or any combination of these possibilities. Cutaneous lesions usually present because of cosmetic complaints related to skin discoloration. The diagnosis is made by inspection of the lesion and by recognizing associated stigmata of syndromes that contain a capillary angioma as a constituent part.[19] Deep capillary angiomas usually present as a mass that has been present since birth. The natural history of these lesions varies. They may be static, they may grow larger because of hemodynamic change (not cell proliferation), or they may involute.[15,16,20,21]

Deep capillary angiomas within a limb are frequently associated with enlargement of that extremity. Parks and Weber termed this phenomenon *hemangiectatic hypertrophy*.[22] Vanderhoeft has shown that limb hypertrophy results from altered hemodynamics either by hyperemia or passive congestion. An increase in bone length is due to hyperfusion of the epiphyseal cartilage. Increased bone thickness is secondary to periosteal stimulation by increased blood flow.[23–25]

Microscopically, a capillary angioma is represented by large vascular cavities grouped in lobules or scattered in tissues. The wall is a single tract of endothelial elements, and capillary hemangiomas are considered huge capillaries, distended by altered hemodynamics.

Imaging studies of capillary angiomas have been carried out using angiography, ultrasonography, radionuclides, computed tomography (CT), and magnetic resonance imaging (MRI).[26–43] The goals of noninvasive imaging are 1) to detect the presence of a lesion; 2) to delineate accurately the extent and location of the abnormality and its relationship to adjacent structures; and 3) to uncover the underlying nature of the lesion.

An angioma is seen on CT scans as a well-circumscribed "soft tissue" density mass. Invasion of adjacent structures does not occur and is not consistent with the benign nature of this lesion. Calcifications, probably representing phleboliths, may be present.[26] The vascular nature of the lesion can be demonstrated with the use of contrast enhancement. The dynamic technique—a rapid series of images following a timed and measured bolus of contrast material—is particularly useful in demonstrating the hypervascularity of angiomatous masses. Benign neoplasms may be hypervascular as well, whereas malignant tumors are usually avascular or hypovascular.[27]

Magnetic resonance imaging may be the best noninvasive means for the study of a deep angioma. It produces images in the axial, sagittal, and coronal planes without using contrast material or ionizing radiation. On T_2 weighted images, the blood within an angioma produces a markedly higher signal than surrounding tissues, which allows for accurate identification of the extent of the lesion and understanding of its relationship to other structures.

Angiography may not yield complete delineation of a capillary angioma. One may note an increase in the number of arterial vessels in the region of the lesion. These branches are usually of small size. There may be no opacification of the draining veins, even if they are dilated (Fig. 85–2). Burrows et al.[44] have shown that vascular malformations may be differentiated from neoplastic hemangiomas angiographically. Hemangiomas show the presence of a well-circumscribed tissue stain usually arranged in a lobular pattern, which is not a feature of the capillary angioma type of vascular malformation (Figs. 85–3 and 85–4). Careful, selective angiography is still important in the evaluation of capillary angioma. One may discover the feeding vessels of the lesion, ascertain that a vascular lesion producing arteriovenous shunting is present, and add to the understanding of the underlying nature of the mass to plan therapy.

Macrofistulous Arteriovenous Fistula

Macrofistulous malformations encompass those vascular malformations made up of one or more feeding arteries joined to draining veins by an intervening tangle of ambiguous vascular channels. The walls of the intermediate channels may appear arterial, venous, or have features of both types of vessels, all of which contain oxygenated blood.[45–47] These anastomotic channels may be several millimeters in diameter and up to several centimeters long[47] (Figs. 85–5, 85–6, and 85–7).

Arteriovenous fistulae may occur anywhere within the body, although they are probably most common in the extremities (Table 85–3).[48,49] They usually present as a nontender swelling, associated with a thrill and bruit. In an extremity, dilated veins are usually present, and there is usually no change in skin pigmentation. The size of the extremity may vary; the limb may be normal, smaller, or larger than the opposite limb. Small size results from ischemia of tissues distal to the shunt.

Depending on the site of the lesion, presentation may be due to spontaneous hemorrhage or to alteration of physiologic function. For example, arteriovenous malformations of the gastrointestinal tract frequently present as bleeding. Lesions of the brain may manifest with headache, seizures, or hemorrhage. Arteriovenous malformations of the kidney may present with hypertension. Lesions in the extremities often present with claudication. Unlike acquired arteriovenous fistulae, congenital macrofistulous malformations do not usually produce systemic hemodynamic effects.[49]

Noninvasive imaging by ultrasound, CT, and MRI will demonstrate the presence of a vascular mass associated with arteriovenous shunting of blood. Magnetic resonance imaging is the method of choice for noninvasive imaging. T_2 weighted images show the relationship of the vascular malformation to adjacent soft tissue structures. T_1 weighted images are especially useful in showing the relationship of the malformation to adjacent bone. Further discussion of MRI can be found in Chapters 37 and 51. The depiction of the involvement of these structures is extremely helpful in planning therapy.[50]

Table 85–3. Arteriovenous Fistulae: 10-Year Experience at the Mayo Clinic[48]

	Congenital	*Acquired*
AV fistulae of the extremities	80	17
Aorta–inferior vena cava fistulae	0	7
Pulmonary AV fistulae	47	0
Renal AV fistulae	0	6
AV fistulae of the portal system	0	1
AV fistulae of the neck and face	11	4
Pelvic AV fistulae	1	5
AV fistulae of the chest wall	0	2
Total	139	42

(*Source:* Gomes, M.M.R., and Bernatz, P.E.: Arteriovenous fistulas: A review and ten year experience at the Mayo Clinic. Mayo Clin. Proc., *45*:81, 1970.)

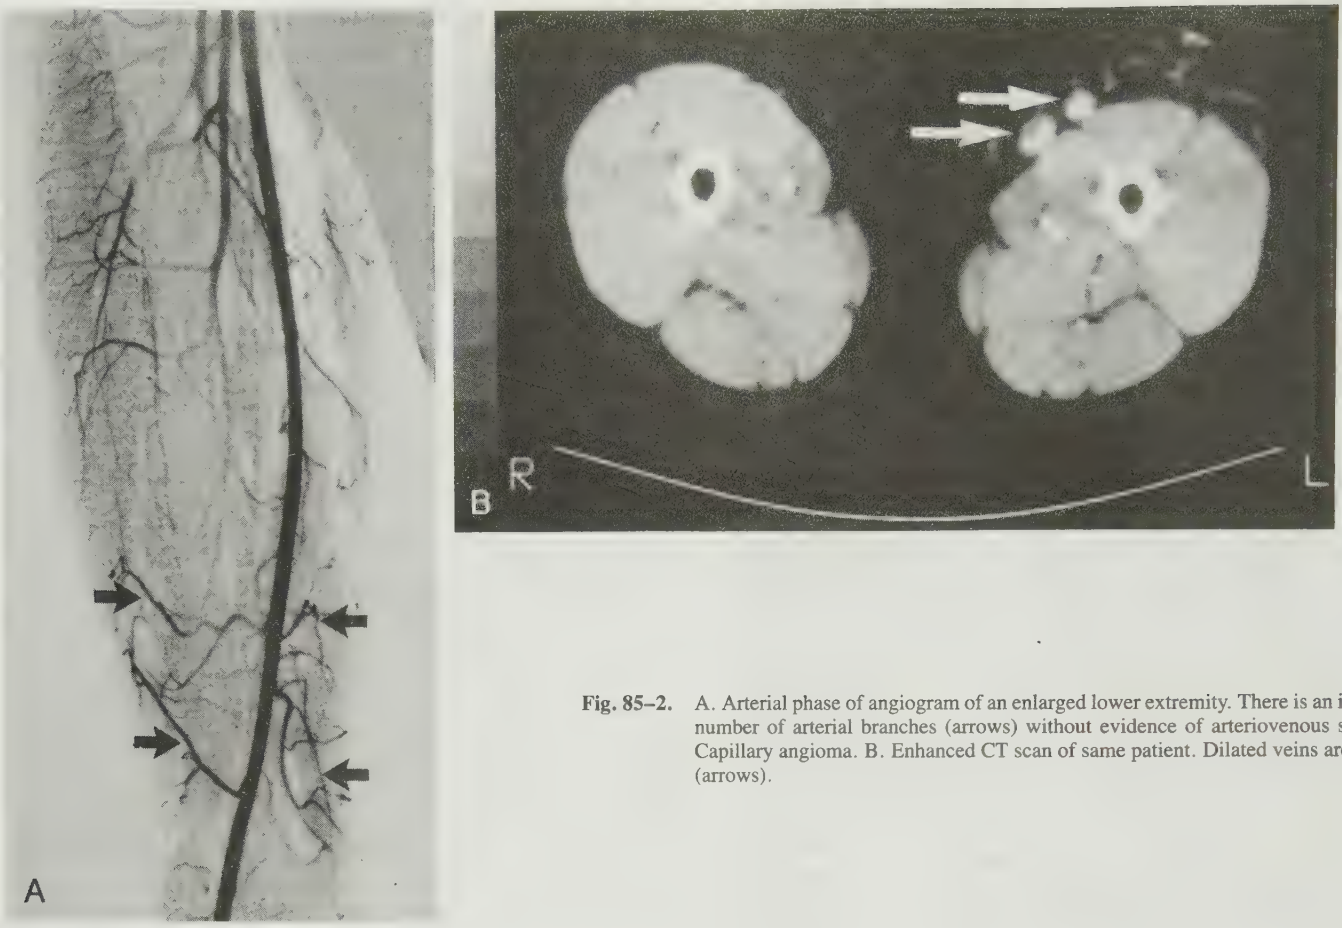

Fig. 85–2. A. Arterial phase of angiogram of an enlarged lower extremity. There is an increased number of arterial branches (arrows) without evidence of arteriovenous shunting. Capillary angioma. B. Enhanced CT scan of same patient. Dilated veins are evident (arrows).

Angiography of these lesions characteristically shows multiple, dilated, tortuous arterial feeders that enter a tangled mass of anastomotic vessels. Multiple dilated and tortuous draining veins appear almost immediately.

Views in multiple projections are usually required to deal with the considerable overlap of vessels. Subtraction of the films is useful, especially if the malformation is adjacent to bone. The flow through the lesion is rapid, and filming sequences should be at least two per second or faster. In unfolding the anatomy of a lesion, a helpful technique is to make serial subtractions. By this method a reverse film is made of each film in the series; this film is then used as a subtraction mask over the subsequent film. The resulting image shows what new vessels were opacified in that smaller unit of time. Digital subtraction angiography is advantageous because 1) it provides immediate subtracted images; 2) repeated studies in multiple projections can be rapidly obtained; and 3) dilute mixtures of contrast material can be used, thus conserving contrast dose and minimizing discomfort.

Truncal Arteriovenous Fistula

Truncal arteriovenous fistula results from abnormal communication of mature arteries and veins without an intervening anastomotic channel. A good example of this malformation is the "Vein of Galen Aneurysm." In many of these lesions the terminal ends of the anterior cerebral artery and branches of the posterior cerebral arteries join directly to the Vein of Galen, creating an enormous arteriovenous shunt. Other examples of truncal arteriovenous fistulas have been found between the vertebral artery and adjacent to the deep cervical vein, and between terminal branches of the external carotid arteries and the superior sagittal sinus. Large truncal fistulas are usually associated with neonatal congestive heart failure.

Angiographically, the lesions are seen as dilated arterial feeders that join directly to extremely dilated draining veins. The shunt is usually large and the circulation time shortened (Figs. 85–8 and 85–9).

Digital subtraction angiography is especially useful in these cases because one is often dealing with a small infant in congestive heart failure, which makes economy of contrast material an absolute requirement.

TREATMENT

In general, surgical cure of vascular malformations is impossible unless the lesion is simple or very well circumscribed.[51–53] Surgical difficulties have led to the development of nonsurgical modes of therapy, as well as a philosophy of conservative, watchful waiting.

Approximately 50% of deep capillary angiomas undergo spontaneous involution. There have been reports of the use of systemic steroids to bring an enlarging angioma under control.[54–57] The mechanism by which steroids affect vascular malformations is not

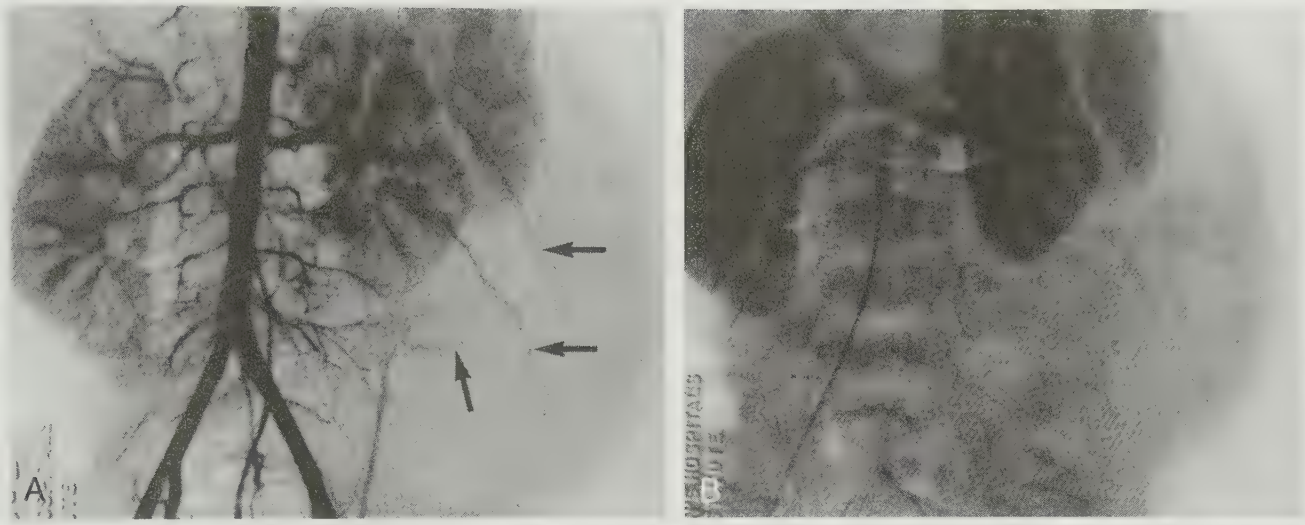

Fig. 85–3. A. Arterial phase angiogram of mass in left flank. Numerous arterial feeders (arrows) without early draining vein. Capillary angioma. B. Later phase shows diffuse, disorganized stain without evidence of any draining veins.

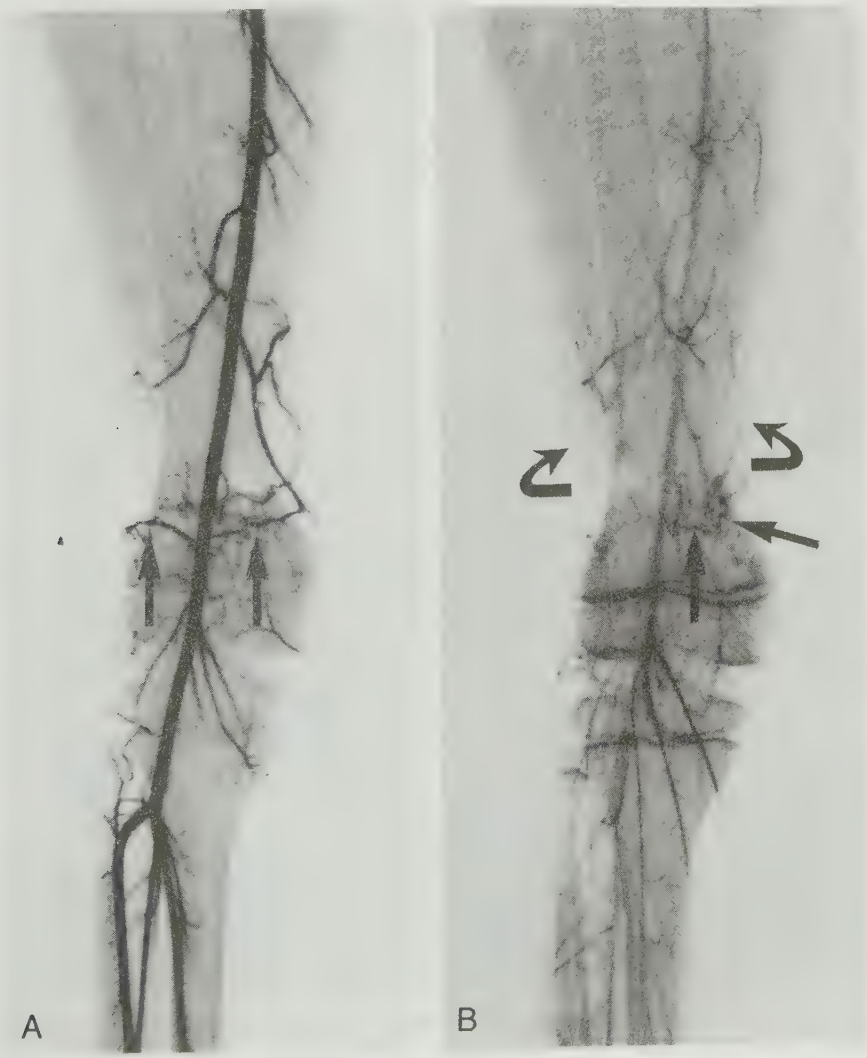

Fig. 85–4. A. Arterial phase of angiogram of enlarged lower extremity. Numerous, slightly dilated arterial vessels (arrows). No definite early draining vein. B. Later film shows early draining (curved arrows) and persistent stain in ambiguous connecting vessels (straight arrows). This is a capillary angioma with some macrofistulous characteristics.

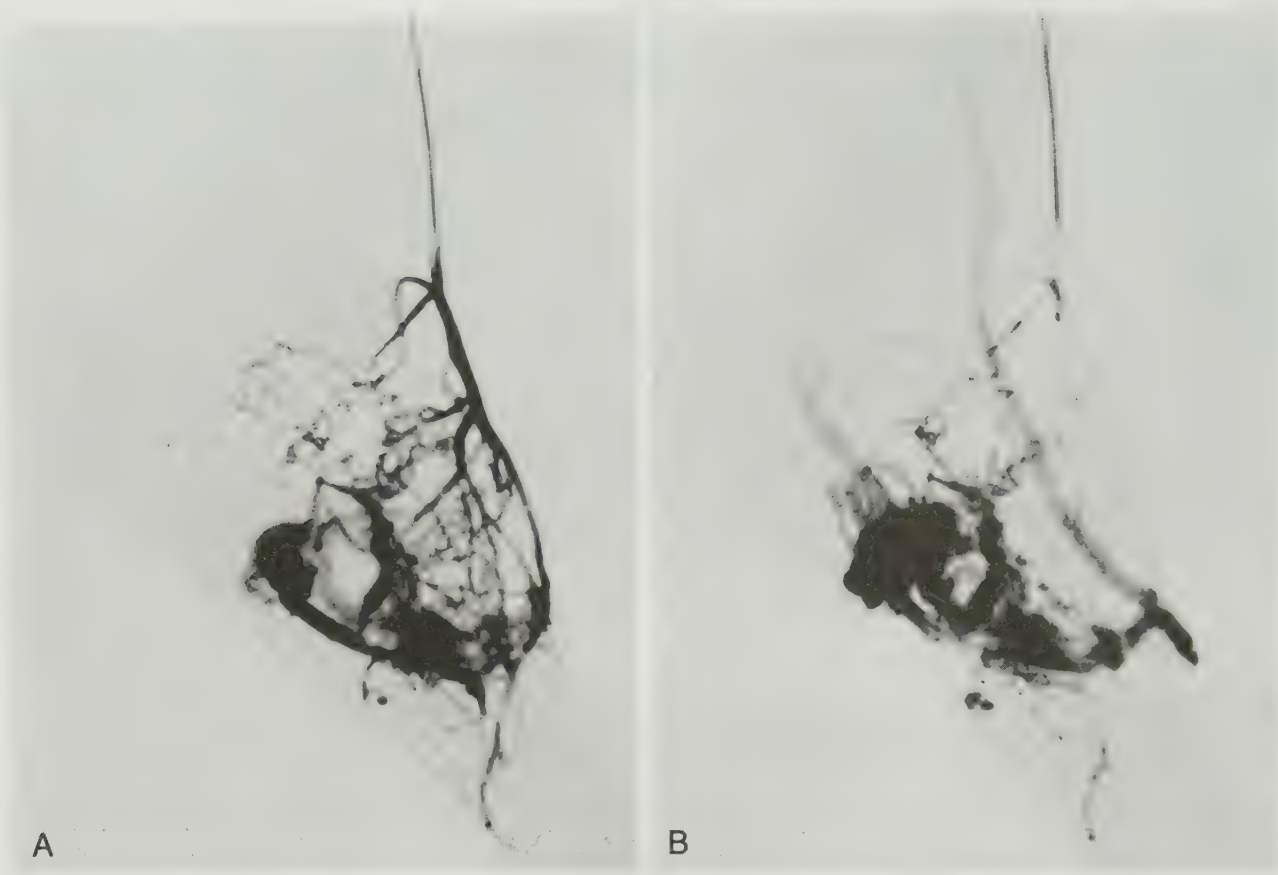

Fig. 85–5. A. Macrofistulous arteriovenous fistula of foot with numerous dilated feeding arteries. Immediate opacification of anastomotic channels and dilated draining veins. B. Venous phase showing densely opacified nidus and dilated draining veins.

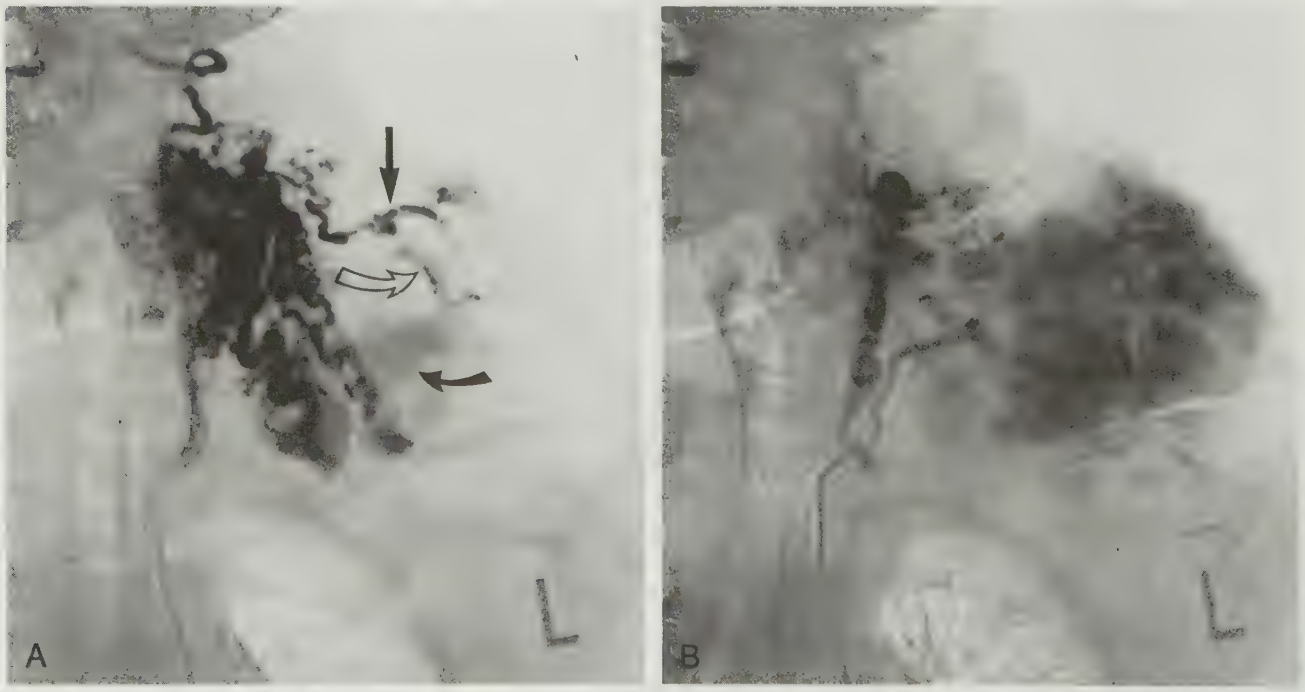

Fig. 85–6. (A) Macrofistulous lesion of neck, selective vertebral angiogram. Numerous dilated arterial feeders (solid arrow), immediate opacification of anastomotic channels (open arrow), and dilated veins (curved arrow). (B) Venous phase shows markedly dilated draining veins.

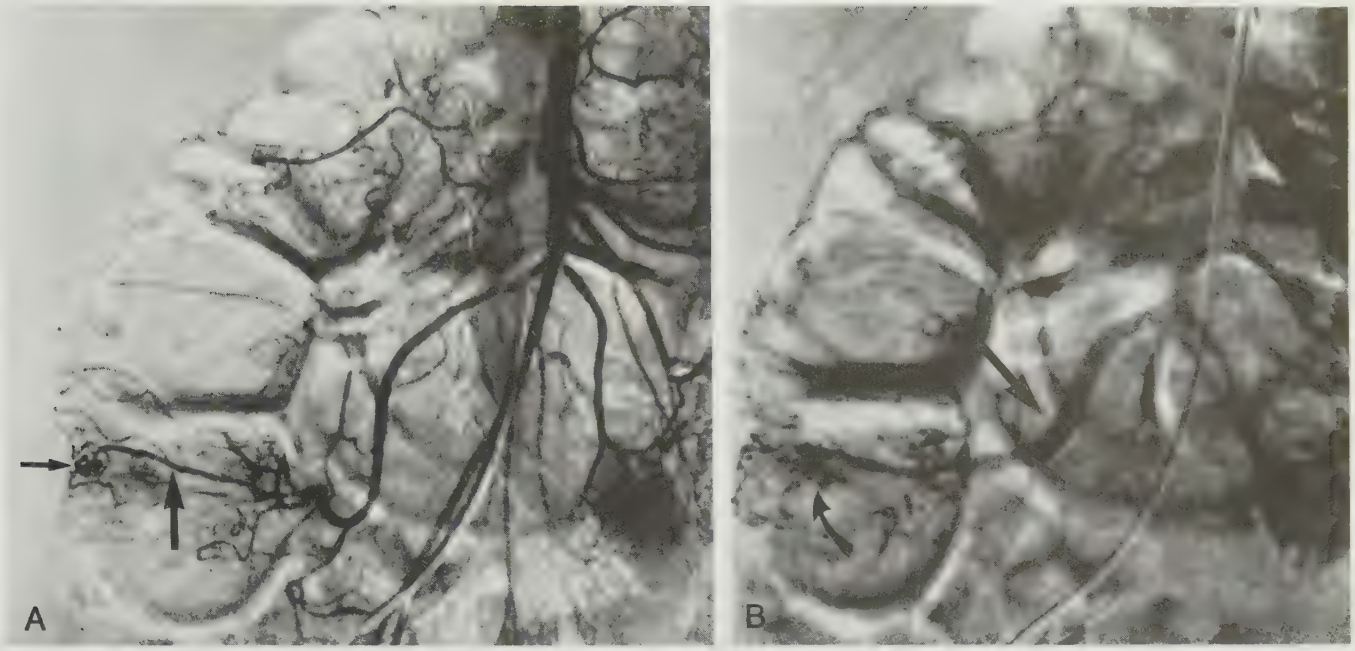

Fig. 85–7. (A) Arterial phase, selective superior mesenteric angiogram. Multiple dilated arterial vessels in cecum without immediate opacification of draining vein (arrow). (B) Venous phase shows dilated draining vein (arrows) and persistent stain in anastomotic vessels (curved arrows). This is a slow flow macrofistulous lesion.

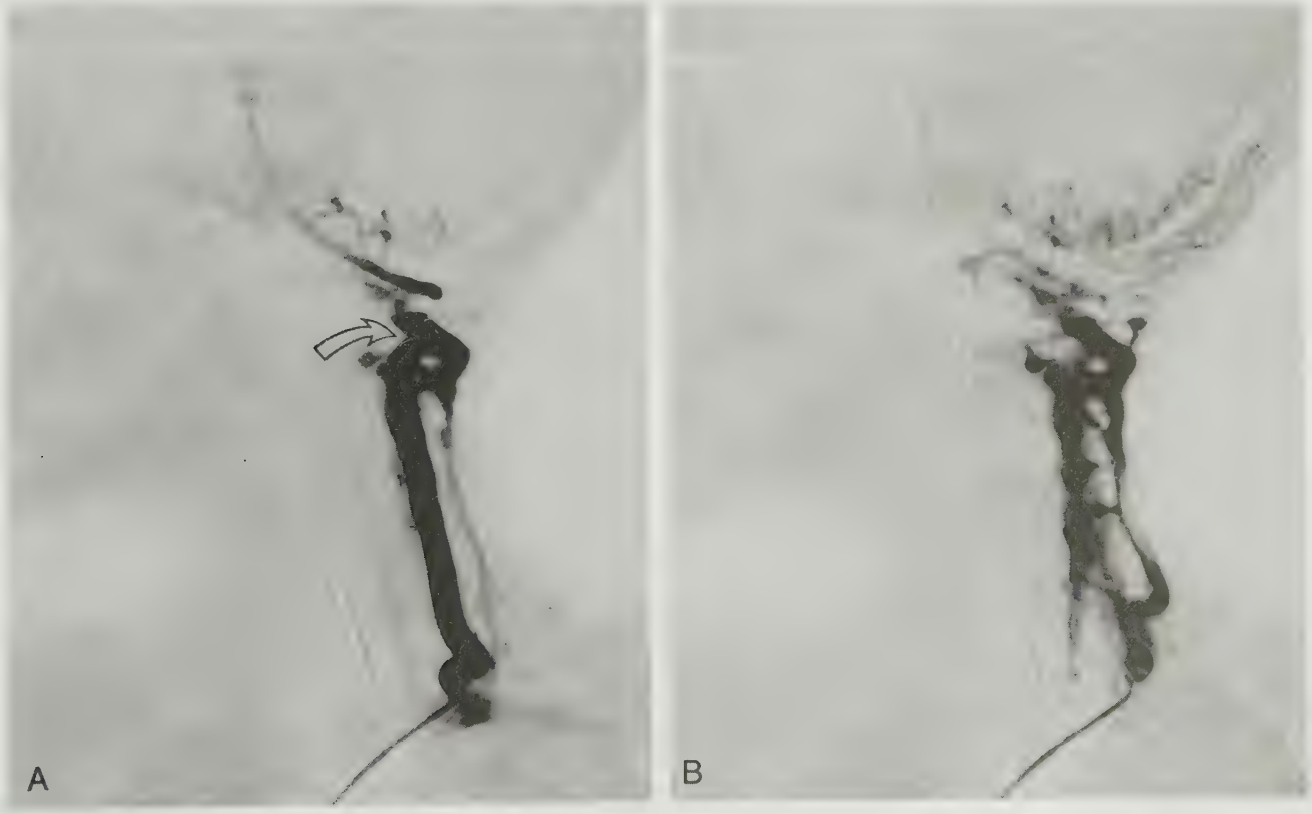

Fig. 85–8. (A) Truncal arteriovenous fistula. Selective vertebral injection shows dilated vertebral artery connected directly to enlarged cervical vein (arrow marks fistula). (B) Venous phase shows dilated venous plexus.

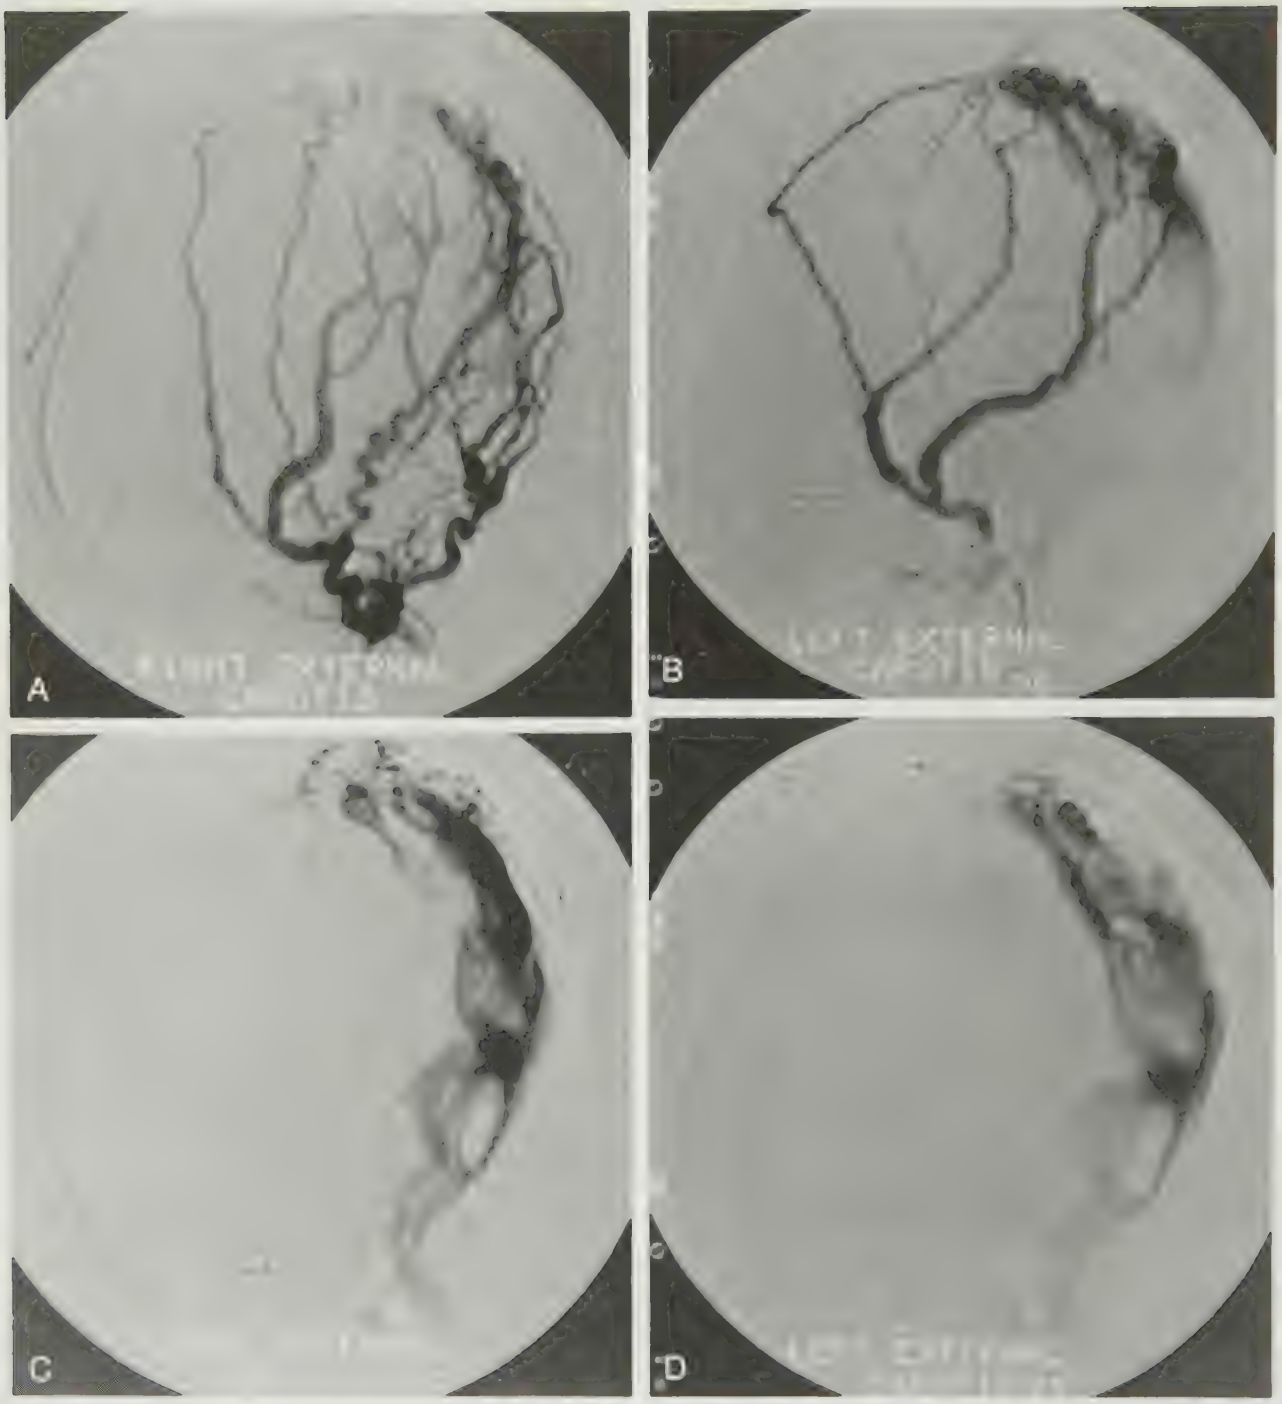

Fig. 85–9. Lateral views of right (A) and left (B) external carotid angiography show multiple dilated branches of both vessels. There are both truncal and macrofistulous connections between the external carotids and the superior sagittal sinus. (C and D) Venous phase shows some persistent opacification of anastomotic vessels and enormous dilation of superior sagittal sinus.

known. Hypotheses include alterations of endothelial cell metabolism and the incitement of precapillary arterial constriction.[56,57]

Transcatheter embolic therapy has emerged as a valuable method of treatment of vascular malformations. This method has several advantages. Percutaneous transcatheter treatment is less invasive than surgery and seeks to occlude the deep anastomotic channels that constitute the nidus of vascular malformation. Embolization can be used alone repeatedly as a palliative measure to reduce symptoms of a fistula or its interference with the function of an organ. Embolic therapy is also useful in combination with surgery or other forms of therapy.[58–71]

The aim of embolic therapy is to deliver the agent selectively to the vascular malformation as deeply into the lesion as possible without allowing escape of the embolus through the lesion into the venous outflow. In addition, one must make every attempt to deal with all the feeding arterial vessels. As with surgery, cure is not likely, and the therapeutic goal must be realistic. Effective palliation without adverse effect is a reasonable, attainable goal.

Numerous embolic or occlusive agents have been developed. The choice of material will depend on the location, type, and size of the malformation to be treated as well as on the experience of the physician. The longest lasting material that can be delivered as deeply and selectively as possible into the lesion, and which is most familiar to the surgeon, would be the ideal choice in each case.[72–77]

Embolic-occlusive agents fall into the following categories: 1) particulate; 2) liquid or semisolid; 3) detachable balloons; and 4) steel coil.

Particulate Agents

A large number of particulate agents exist[78–81] (Table 85–4). In general, they are readily available, nontoxic, and inexpensive. The longevity of thrombosis produced varies among the agents, ranging from several hours to permanent occlusion. The size of the particles also varies among the agents; some may be readily made into the appropriate size at the time of use.

Liquid and Semisolid Agents

Bucrylate (isobutyl 2-cyanoacrylate) is a member of the alkyl 2-cyanoacrylate family of adhesives. It is an advantageous agent for use in the treatment of arteriovenous fistulae.[82–85] The substance is liquid and low enough in viscosity to be injected through Nos. 2 and 3 French catheters, thus allowing highly selective embolization. The material can be made radio-opaque by mixing with Ethiodol or Pantopaque contrast material, and the polymerization time of the material can be controlled by its dilution with Pantopaque in a range from 1 to 8 seconds.[85] This agent has the advantages of high selectivity and permanence, without toxicity.

Table 85–4. Commonly Used Particulate Embolizing Agents

Agent	*Duration of Occlusion*
Autologous clot	Hours to days
Muscle	Days to weeks
Gelfoam	Weeks
Avitene	Weeks
Silastic, acrylic spheres	Permanent
Polyvinyl alcohol (Ivalon)	Permanent

At present, its use requires investigational exemption from the Food and Drug Administration.

Detachable Balloons

The use of detachable balloons for the embolization of arteriovenous malformations of the nervous system was introduced in Europe in the early 1970s. Since that time the materials and methods for this technique have undergone steady improvement. Balloon sizes range from 1 to 8 mm in diameter, and are placed in final position on a No. 2 French catheter advanced through a No. 5 French catheter, which is inserted through a No. 9 French introducer.[86–89] Once in place, the balloon is filled with radiopaque contrast material or silicone, then detached by tugging sharply on the No. 2 French catheter. The balloon should remain inflated indefinitely; its radiopacity will keep a record of its position. The disadvantage of this system is that the occlusion is made in the feeding vessels proximal to the deep anastomotic portion of the vascular malformation. The balloon thus exerts an effect somewhat like a surgical ligation. Balloons may be useful to block the larger vessels after the deep portion of the lesions have been dealt with using particles or bucrylate.

Steel Coils

Steel coils were developed by Anderson, Wallace, and Gianturco, and were first used in the late 1970s to occlude acquired arteriovenous fistulae.[90–92] The device consists of a stainless steel coil with strands of wool attached to promote thrombosis. The coils are supplied in straightened form in small holders. After satisfactory catheter position is obtained, the holder is placed through the stopcock and the coil is pushed through the catheter and out into the vessel with a guide wire. On emerging from the catheter, the coiled position is assumed in 3, 5, or 8 mm diameters, depending on the size coil used.

Like balloons, steel coils are useful to block the more proximal portions of feeding arteries but cannot reach deep arteriovenous communications in tangled macrofistulous arteriovenous fistulae. Their large size makes them useful for obliterating larger fistulae, particularly congenital truncal arteriovenous fistulae or acquired traumatic fistulae. Use of steel coils requires experience and expertise. It is wise to practice with them in vitro or in a laboratory setting before using them clinically.

UNIT 5

INFLAMMATORY CARDIOVASCULAR DISEASE

CHAPTER 86

Acute Rheumatic Fever

Galal M El-Said
Khalid A Sorour

The importance of acute rheumatic fever (RF) and rheumatic heart disease (RHD) lies in its incidence, prevalence, mortality, disability, and cost to the community.[1]

Rheumatic fever is still the most common cause of heart disease in many developing countries. For example, in Egypt,[2] India,[3] and South America,[4] rheumatic heart disease is still the predominant form of heart disease in children. In the United States, although the prevalence is low and still decreasing in comparison to that in developing countries, rheumatic fever maintains its position as the leading cause of postnatally acquired heart disease in children.[5] An increase in prevalence in rheumatic fever has been reported in many areas of the United States, an eightfold increase in the annual incidence over the past decade being reported in the intermountain west.[6]

Rheumatic fever, which consists of delayed nonsuppurative sequelae of upper respiratory tract infection with group A beta-hemolytic streptococci, is a diffuse inflammatory disease of the connective tissue involving chiefly the heart, joints, brain, blood vessels, and subcutaneous tissue.[7]

"The term acute rheumatic fever today seems to be a misnomer, for it on occasion may be neither acute, rheumatic nor febrile."[7] Although the term emphasizes the involvement of the joints, the major importance of the disease comes from the involvement of the heart. In 1884, Lasegue described the fact that "rheumatic fever is a disease that licks the joints but bites the heart."

Recognition of the relationship between rheumatic fever and infection with group A beta-hemolytic streptococci has resulted in a clearer understanding of the epidemiology and natural history of the disease as well as in a more precise delineation of the clinical entity and practical approaches to its control.[7-9]

EVIDENCE THAT STREPTOCOCCUS IS THE INITIATIVE AGENT

The evidence that group A beta-hemolytic streptococcus is the sole initiative agent leading to RF and its recurrences is indirect. The organism cannot be recovered from RF lesions, and there is no satisfactory experimental model for the disease.

Epidemiological Evidence

Several epidemiological studies over many years have demonstrated sequential relationship between the outbreaks of streptococcal pharyngitis and rheumatic fever.[10] The several factors (environmental, host, and bacterial) that play a role in the development of RF are related to the incidence and severity of preceding streptococcal infections.

Immunological Evidence

Initial as well as recurrent attacks of RF do not occur without a streptococcal antibody response. The magnitude of the antibody response is also related to the attack rate of rheumatic fever and to recurrences following streptococcal pharyngitis.[11]

Clinical Evidence

Septic sore throat preceding acute rheumatic fever and its recurrences has been recognized clinically for over 100 years. It may be difficult to establish that streptococcal pharyngitis is the sole etiologic agent, since inconsistencies in this relationship have

been reported.[12,13] Rheumatic fever and its recurrences may occur without recognizable preceding sore throat.

Prophylactic Evidence

Convincing evidence is provided by the prevention of both initial and recurrent attacks of rheumatic fever by penicillin therapy.[11]

STREPTOCOCCUS: THE INITIATING AGENT

Streptococci are a group of gram-positive microorganisms that are widely prevalent in nature. They are spherical or oval in shape. When cultured, they are arranged in chains. Some are members of normal human flora. Others are associated with important human diseases caused by infection or sensitization by streptococci.

The streptococcus (Fig. 86–1) is composed of a core of cytoplasm surrounded by a cytoplasmic membrane and a cell wall. The cell wall, in turn, is surrounded by a capsule that constitutes the external surface of the organism.

The ability of streptococci to hemolyze red cells to varying degrees is one basis for their classification. Alpha-hemolytic streptococci form colonies surrounded by an ill-defined greenish halo in which hemolysis is incomplete. Beta-hemolytic streptococci produce a clear zone of complete hemolysis on blood agar. These must be carefully differentiated from other hemolytic species such as other streptococci and gram-negative organisms by colony characteristics and Gram stain. Gamma streptococci do not have any effect on blood-containing media.

Beta-hemolytic streptococci were classified into several groups by Lancefield, who labeled them alphabetically according to a polysaccharide antigen in the carbohydrate layer of the cell wall. Group A streptococci have also been called Streptococcus pyogenes. This group of streptococci is responsible for over 90% of human streptococcal infections and inflammatory syndromes, among which are acute rheumatic fever and acute glomerulonephritis. The group A carbohydrate moiety of the cell wall has been shown to be antigenically similar to glycoproteins of bovine and human cardiac valves.[14] This relationship has led to speculation about a role for this cell wall component in the pathogenesis of valvular damage in rheumatic fever.

Beta-hemolytic streptococci of groups C, G, and B are carried persistently in the throats of some people. These groups may cause unnecessary concern when isolated from throat cultures if the identity of the group is not determined.[7]

The biology of the group A streptococcus cannot be understood without a thorough knowledge of the structure of its cytoplasmic membrane, cell wall, and external capsule. Many recent studies have paid great attention to this last feature.[15–17] The capsule, which is the outermost part of the cell, is formed of hyaluronate. It is nonantigenic and chemically indistinguishable from hyaluronic acid of humans and other mammals. Hyaluronate is antiphagocytic but is of doubtful significance in human infections because most normal human sera contain a factor that neutralizes its effect.[18]

The other protein layers and their fimbriae are attached to the surface of the organisms and contain the M-protein and lipoteichoic

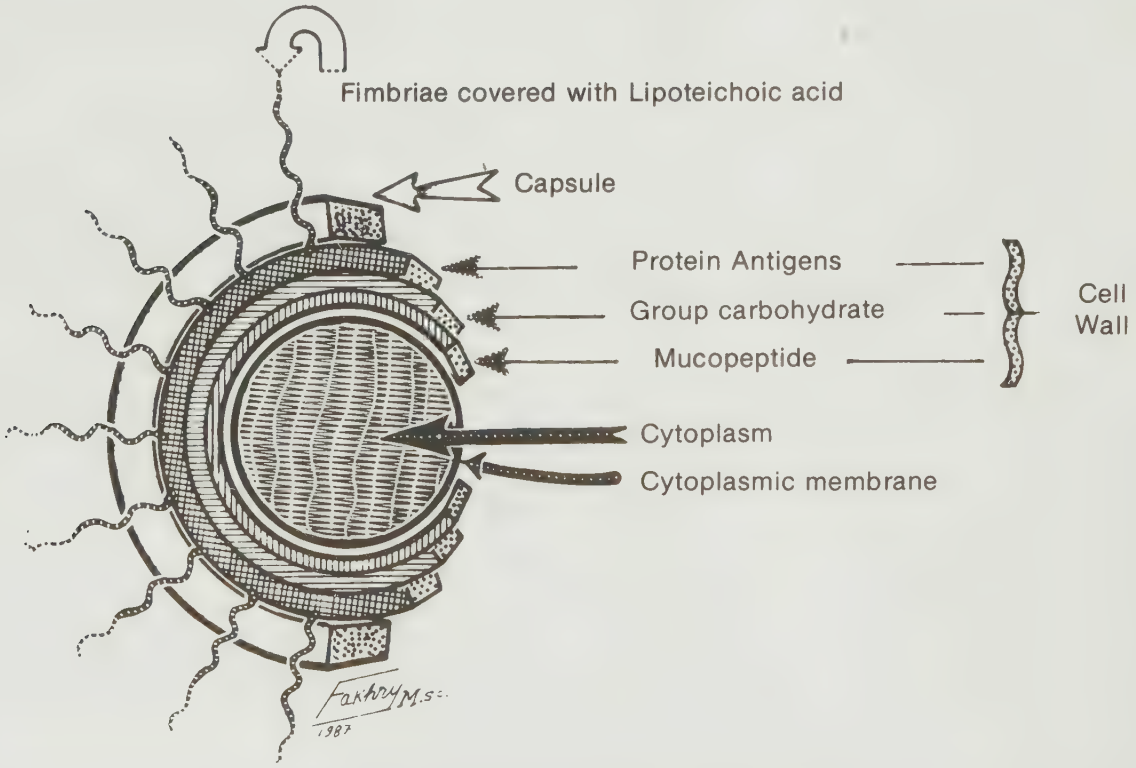

Fig. 86–1. Schematic diagram showing the structure of the streptococcal cell wall. The fimbriae covered with lipoteichoic acid help the organism to adhere to the throat epithelium (adherence factor). These fimbriae, being projections from the protein layer of the cell wall, contain M-protein, the virulence factor. Each of the different layers of the cell wall and the cytoplasmic membrane have been shown to cross-react with different antigens from different structures of the mammalian heart, including the human heart.

acid. The M-protein provides the streptococcal cell antiphagocytic properties. It is a primary virulence factor and induces the formation of type-specific antibodies, which are the basis of type-specific immunity. M-protein is a coiled molecule (double alpha-helix) with striking physicochemical similarity to mammalian tropomyosin.[19] Evidence has been presented that a protein closely associated with the M-protein cross-reacts antigenically with an antigen in heart muscle.[20] Other proteins, T and R, may be associated with the M-protein. Immunity to virulent strains of group A streptococci is related to the production of antibodies to the specific M-protein.[21] Such antibodies persist for many years following pharyngeal infections. Should these antibodies disappear from the circulation with time, they can be quickly recalled by minor antigenic stimuli.[22] So it appears that the type specific immunity is lifelong and that reinfection with the same type of group A streptococcus is extremely rare. Group A streptococci become vulnerable to phagocytosis once they have been exposed to their specific anti-M antibody, and they are rapidly destroyed by human blood phagocytes. As children approach adolescence, streptococcal throat infections become less frequent, whereas immediate and delayed skin allergy to streptococcal products becomes increasingly severe. The multiplicity of M-type group A streptococci and allergic reactions to epitopes of M-proteins are among the reasons why an effective vaccine has not been produced to date.[7]

The mucopeptide innermost layer of the cell wall is responsible for the shape of the cell. The cytoplasmic membrane is an antigenic lipoprotein, which cross-reacts with several mammalian tissue antigens, including glomerular basement membrane and sarcolemmal antigen.

Cross-reacting antibodies occur because of molecular mimic between the human host and the cell wall of the streptococcus and the cytoplasmic membrane.[23] Autoantibodies have been shown in sera of patients with RF to cardiac, skeletal, and smooth muscles, heart valve fibroblasts, neurons in basal ganglia, some determinants of connective tissue, thymus, and lymphocytes.[24] Such antibodies were detected in higher titres in RF patients than in patients with uncomplicated streptococcal infections. M-serotypes 5, 6, and 19 show cross-reactive immunity with cardiac myosin.[25]

The streptococcal fimbriae also contain lipoteichoic acid, which is essential for the organism's adherence to the epithelial cells of the oral mucosa[26] and respiratory tract.

In addition to the cell wall antigens described, there are many extracellular products that are elaborated by group A streptococci. These products have a wide variety of biological properties. Some of these products are sensitizing agents, some are cytotoxic, some are enzymes, some are toxins, and some have structural similarity to human host tissues.

Among the *sensitizing substances* is a non-type-specific protein antigen associated with M-protein,[23] which has been considered responsible for the delayed hypersensitivity of humans to M-antigen vaccines. In addition, streptolysin O has been shown to cause anaphylactic reactions in previously sensitized animals.

Cytotoxic substances include streptolysin O, which causes cytolysis of erythrocytes and has a severe cardiotoxic effect on rabbit, rat, and guinea pig hearts. The pathology is inhibited to a great extent by skin lipids. This might explain the absence of rheumatic fever after skin infections.[27] Erythrogenic toxin causes the rash characteristic of scarlet fever. Erythrogenic toxin is also antigenic, giving rise to the formation of specific antitoxins.

Several enzymes are produced by the streptococci. They are not type-specific. All, with the exception of streptolysin S, are antigenic. Antibodies to these enzymes can be measured in blood and are used to diagnose recent streptococcal infection.

Hemolysins (Streptolysins)

Streptolysin O, which is active only in the reduced state, is rapidly inactivated when oxidized. It elicits formation of antistreptolysin O, which blocks hemolysis by this antigen. High levels of antistreptolysin O (in excess of 160 to 200 Todd units) are considered abnormal and suggest either recent infection with streptococci or persistently high antibody level following an earlier exposure in a hypersensitive person.

Streptolysin S is an oxygen-stable product that causes hemolysis on blood agar. It is not antigenic.

Streptokinase (Fibrinolysin)

Streptokinase transforms the plasminogen of human serum to plasmin, an active proteolytic enzyme that digests fibrin and alters proteins. Streptokinase can elicit the formation of antistreptokinase.

Hyaluronidase

Hyaluronidase is an enzyme that splits hyaluronic acid, an important component of the ground substance of connective tissue, thereby aiding in the spread of infection (spreading factor). Hyaluronidase elicits formation of antihyaluronidase.

Deoxyribonucleases

There are four deoxyribonucleases (A, B, C, and D), all of which are antigenic. Deoxyribonuclease B, also known as streptodornase, is produced in the largest quantities in response to group A streptococcal infections and is the most consistently found deoxyribonuclease.

Diphosphopyridine Nucleotidase

This enzyme is related to the ability of the organisms to kill leukocytes.

Streptococcal Esterase

A rise of antistreptococcal esterase occasionally occurs without a rise of antistreptolysin O in hemolytic streptococcal infections.[28,29]

EPIDEMIOLOGY OF THE STREPTOCOCCUS AND RHEUMATIC FEVER

Many of the epidemiologic features of RF can be explained by the epidemiology of streptococcal infections of the upper respiratory tract.[30] Crowding from inadequate housing is probably the main risk factor in acquiring streptococcal infections and resulting rheumatic fever. The high incidence of streptococcal respiratory infections in the winter and spring probably accounts for the frequency of onset of rheumatic fever in these seasons.[31]

Since Halsey's study in 1921,[32] those who investigate rheumatic fever have been impressed with the diminishing frequency of the disease, particularly in the relatively affluent populations of North America and Europe. Reasons for this decline have been uncertain. Antibiotics for the treatment and prevention of streptococcal in-

fections are likely to have been a factor; however, the incidence and death rate from the disease were decreasing before the introduction of antibiotics. Improved social conditions such as better housing seem likely to have contributed to the decline.

The prevalence of rheumatic heart disease among U.S. schoolchildren has dropped sharply in recent years.[5] However, rheumatic heart disease still constitutes the leading cause of death from heart disease in young people in most parts of the world and continues to be a serious public health problem.[33] The resurgence of rheumatic fever as a clinical problem for pediatric cardiologists in some areas of the United States has been emphasized.

The following are some of the factors that might affect the attack rate of rheumatic fever.

HOST FACTORS

Age, Sex, and Race

Acute rheumatic fever occurs most commonly in the young school-age child and very rarely in infancy. No true differences in sex, race, or ethnic group susceptibility have been established. Living conditions seem to account for apparent increases in susceptibility.

Genetic Predisposition

As early as 1889, Cheadle observed that rheumatic fever can occur in more than one member of the family.[34] Since then, many reports have confirmed familial incidence. Some reports even concluded that susceptibility to rheumatic fever is caused by a single autosomal recessive gene. However, studies of siblings and twins, both monozygotic and dizygotic, have failed to confirm this.[35] The high familial incidence has largely been attributed to the family's standard of living, which has favored a spread of streptococcal infections to more than one member.[36,37] Recently, Ayoub and associates showed findings to support the concept of genetically determined susceptibility to rheumatic fever and particularly to rheumatic heart disease.[38] Their findings could be ascribed to a disease-associated immune-response gene. Two B-lymphocyte alloantigens have also been identified by monoclonal antibodies in the sera of patients with well-documented rheumatic fever in the past. These two antibodies identified approximately 92% of all rheumatic fever patients and suggested the presence of a genetic marker for susceptibility to rheumatic fever.[39]

STRAIN OF STREPTOCOCCI

Although groups C and G streptococci can cause pharyngitis and might provoke an immune response, only group A streptococcal infections of the upper respiratory tract result in rheumatic fever.

It is well recognized that a relatively small number of M types are the most common and dangerous rheumatogenic pharyngeal strains, while others may be nephritogenic. Studies in Memphis have shown seasonal epidemiological separation of acute rheumatic fever from acute glomerulonephritis.[40] Populations in the southern United States in which pyoderma and rheumatic fever both occur show a large number of acute glomerulonephritis cases with virtually absent rheumatic fever in the summer when streptococcal pyoderma is prevalent. In the fall when school begins, acute glomerulonephritis and pyoderma decline rapidly, and acute rheumatic fever appears abruptly. In Trinidad, where both acute glomerulonephritis and acute rheumatic fever are concurrent in the same population with little seasonal variation, cyclical epidemics of acute glomerulonephritis have been repeated[41] but without parallel changes in the incidence of rheumatic fever. A study of streptococcal strains in this population showed a clear distinction between the serotypes associated with glomerulonephritis and those associated with rheumatic fever.[42]

Variations in the rheumatogenicity of group A streptococcal strains may be a factor influencing the attack rate of rheumatic fever. A decline in rheumatic fever has been associated with the decline in prevalence of several of the major M serotype streptococci that are notorious for causing epidemic rheumatic fever (for example, types 5, 14, and 24).[43]

ROUTE OF INFECTION

The necessity for the preceding streptococcal infection to occur in the throat or upper respiratory tract rather than skin is well documented.[44] Several hypotheses have been offered. The possible role of lymphatic connections between the pharynx and the heart has been considered. The embryological derivation of the heart links it with the neck's vascular, lymphatic, and nerve supply. Connection between the tonsils and the heart in human beings has been demonstrated by injection of lymphatic channels in cadavers.[45] The difference in the sites of infection could be the result of a difference in the strains that are commonly pathogenic at these two sites. The feeble antistreptolysin O response with streptococcal infections of the skin[44] and demonstration of skin lipids that inhibit the biological effects of antigenicity of streptococcal enzymes[46] might also explain why rheumatic fever does not occur after streptococcal impetigo. It has been speculated that the streptococcal strains associated with rheumatic fever adhere more avidly to pharyngeal cells of the patients who are susceptible to develop acute rheumatic fever than do strains that are not associated with rheumatic fever.[47]

SEVERITY OF STREPTOCOCCAL INFECTION AND IMMUNE RESPONSE

Antibodies to streptococcal antigens are consistently more elevated in patients with rheumatic fever than in patients who have uncomplicated streptococcal pharyngitis.[48] The rheumatic host might be hyperimmune because of more frequent or more severe streptococcal infections.

Rheumatic fever followed at a fairly predictable attack rate (approximately 3%) in epidemics of frank exudative streptococcal pharyngitis caused by virulent group A streptococci in military populations[30] regardless of age, race, or ethnic group. The most important major predictor of the occurrence of rheumatic fever in these epidemiological studies was the magnitude of the immune response to the antecedent streptococcal infection.[49]

THEORIES ON HOW STREPTOCOCCAL INFECTION CAUSES RHEUMATIC FEVER

Acute rheumatic fever results from the interaction of three main factors: an etiological agent that is the group A beta-hemolytic

streptococcus; an organ site dependence; and a vulnerable host because rheumatic fever occurs only in a small percentage of patients infected with group A beta-hemolytic infections (Fig. 86–2).

Although it is clear that rheumatic fever follows group A streptococcal infection of the upper respiratory tract, how the organism causes rheumatic fever is still unclear.[7] Many theories have been postulated, but none explains the whole story. The difficulties arise because of the inability to definitely relate any known component or product of group A streptococci to rheumatic fever and because of the failure to provide a favorable hypothesis that encompasses all possible factors contributed by the organism as well as the host.[45,50]

So far, there has been no conclusive evidence that rheumatic fever results from persistence of streptococci either in their original or L-forms.[51]

The concept that rheumatic fever is a hypersensitivity reaction was drawn from the analogy of rheumatic fever to serum sickness, including its latent period. The rarity of rheumatic fever among infants suggests that one must experience repeated streptococcal infections to develop sufficient hypersensitivity for rheumatic fever to occur.[52] However, type-specific antibody data from several laboratories indicated that rheumatic patients did not have more frequent streptococcal infections before their first attack.[53] The infrequency of rheumatic fever in infants could also be explained by the rarity of streptococcal infections in this age group.

Much interest has been shown in the possible role of cell-mediated cytotoxic reactions to various streptococcal antigens. Delayed hypersensitivity skin tests to streptococci and their products are generally more intense in rheumatic subjects than in nonrheumatic controls and are particularly intense with extracts of hemolytic streptococci compared with nonhemolytic streptococcal strains.[54] Read and associates[55] showed that patients with acute rheumatic fever have inhibition of migration of leukocytes to group A streptococcal membrane antigens. Patients with uncomplicated streptococcal infections with high antistreptolysin O titers react to these antigens in a normal fashion. This cellular reactivity proved to be specific for group A streptococcal membranes. Group C and D streptococcal membranes elicited normal responses in both rheumatic and nonrheumatic subjects. Sorour and his associates[56] demonstrated significantly increased active T-rosette enhancement to streptococcal antigens among established rheumatic patients as compared with nonrheumatic subjects. Data indicating significant alterations in both helper and suppressor T-cell types in the peripheral blood of children with acute rheumatic fever have been shown to return to normal after recovery.[53,57]

The most popular theory of pathogenesis is that rheumatic fever results from some type of autoimmunity. Numerous reports have shown that the serum of patients with rheumatic fever contains antibodies to heart tissues. These antiheart antibodies are gamma globulins with specificity for cardiac components reacting primarily with the sarcolemma. Their binding is also associated with deposition of large amounts of C_3. Antiheart antibodies occur more frequently in rheumatic fever patients who develop carditis. Massive deposits of gamma globulins have also been identified in the hearts of children who died of rheumatic carditis. Pericardial tissue has shown extensive deposition of IgG, IgM, and C_3, a finding suggesting an immune mechanism for the pericarditis of acute rheumatic fever.[58] Kaplan and associates, as well as several more recent reports, have demonstrated that rabbit antisera against certain group A streptococci react with human heart preparations,[59,60] indicating cross-reaction between the streptococcus and human heart. Cardiac damage by trauma or ischemia results in biochemical changes manifested by the production of autoantibodies.[60] This raises the question: Is the antiheart antibody in rheumatic carditis the result or the cause of tissue injury? Antibodies to other tissues have been found in the sera of patients with rheumatic fever. A 95% incidence of smooth muscle antibody was found in sera from 55 rheumatic fever patients compared to 12% from overall hospital patients.[61]

To summarize (Fig. 86–2), one can conclude that for acute rheumatic fever to occur, a certain strain of group A beta-hemolytic

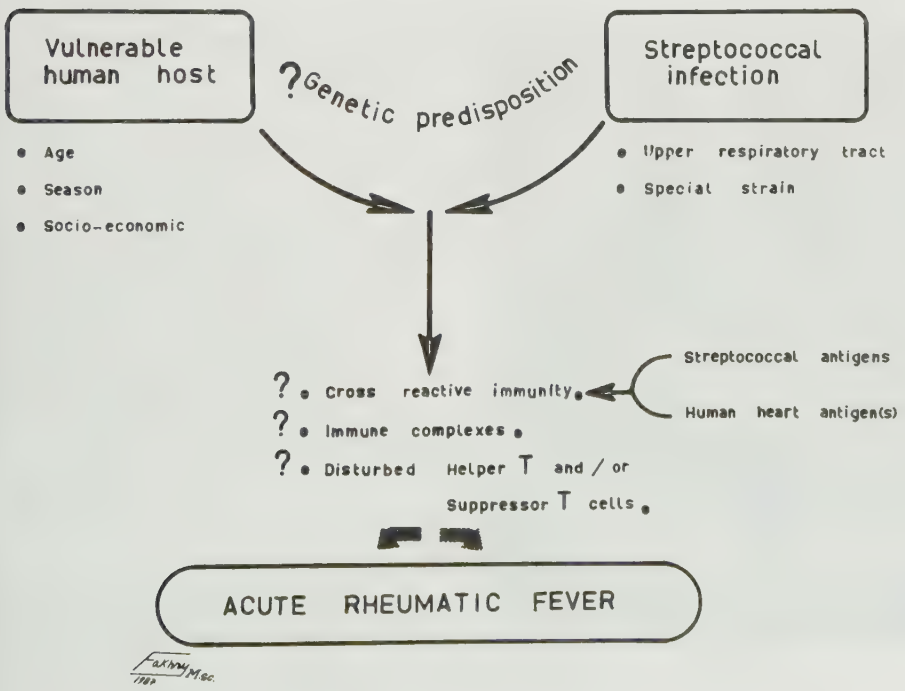

Fig. 86–2. Diagram showing the factors leading to rheumatic fever. The question marks show the as yet rather obscure factors that are possibly related to the complex pathogenesis of rheumatic fever.

streptococcus must infect the upper respiratory tract of a vulnerable host. Age, season, and socioeconomic standards are responsible for the frequency and spread of such streptococcal infections. The possible genetic predisposition to be afflicted with rheumatic fever, added to the above, creates the perfect human host. The molecular mimicry between certain parts of the streptococcus and tissues of the host may lead to cross-reactive immunity, in which the immune system will damage both the streptococci and certain tissues of the patient, especially the heart. This, together with the disturbed helper and suppressor T-cells, may bring about a "final blow" and lead to the complex immune system disturbance that results in acute rheumatic fever and its sequelae of cardiac damage.

PATHOLOGY OF RHEUMATIC FEVER

Rheumatic fever is characterized pathologically by two main lesions in the connective tissues occurring particularly around small blood vessels.

The first and the earliest lesion is exudative, degenerative, and inflammatory. This consists of edema of the ground substance and fragmentation of collagen fibers. There is cellular infiltration by T-lymphocytes, macrophages, B-lymphocytes, and mast cells. Scattered deposits of eosinophilic granular material (fibrinoid) occur in the ground substance. This exudative-degenerative inflammatory lesion contributes to transitory manifestations of rheumatic fever and responds to anti-inflammatory agents. This early phase lasts two to three weeks and is followed by the second lesion.

The second characteristic lesion of rheumatic fever is a proliferative one that may persist for many months or years.[62] The characteristic proliferative lesion is the Aschoff's nodule. The proliferative lesion probably does not respond to the anti-inflammatory agents. The myocardial Aschoff's nodule (Fig. 86–3) is usually oval in shape. There is a paravascular aggregation of large multinucleated cells in a basophilic cytoplasm. Many of these cells have a characteristic owl-eye nucleus. There usually are rosettes around an avascular core of fibrinoid or necrotic protoplasm.

The Aschoff's nodule, from its description in 1904, was thought to arise from connective tissue until Murphy challenged this traditional concept in 1960[63] and postulated that it resulted from injury to the cardiac muscle fibers. Three years later, Wedum and McGuire[64] suggested that the Aschoff's nodule is from neither connective tissue nor cardiac muscle but is formed because of injury to the endothelium of cardiac lymphatics that leads to blockage of the lymphatics. In 1973, Hutchins and Paige[65] suggested that Aschoff's nodules might be derived from nervous tissue, since they noticed that the Aschoff's cells resembled the Schwann cells of normal cardiac nerve fibers and that Aschoff's nodules are formed at the termination of small nerves.

Not only is the origin of Aschoff's nodules controversial, but the functional impact of nodules on the heart and relation to the course and severity of rheumatic attacks are not clear.[63,66] The persistence of Aschoff's nodules for many years after a rheumatic attack is well documented. Biopsies of left atrial appendages obtained during mitral valve surgery for mitral stenosis have demonstrated the persistence of Aschoff's nodules in patients who no longer have clinical or laboratory evidence of rheumatic activity or recent streptococcal infection.[67] The persistence of Aschoff's nodules might be related to progressive fibrosis and stenosis of the mitral valve.

The three layers of the heart may be involved, leading to what is known as "rheumatic pancarditis."

Pericarditis

Rheumatic pericarditis consists of a serofibrinous pericarditis with effusion. The pericardium has a characteristic shaggy appearance caused by deposition of fibrin on its surface (Fig. 86–4). With healing, fibrosis and adhesions develop that may partially or completely obliterate the pericardial space. Constriction does not occur.

Myocarditis

The myocardium is affected not only by Aschoff's nodules but also by interstitial inflammation and myocardial cell damage. In-

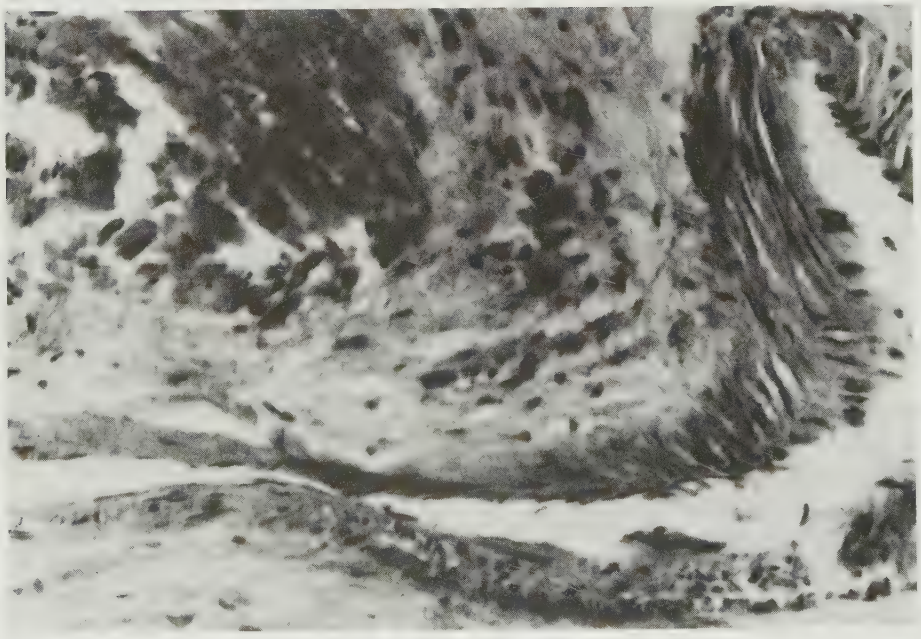

Fig. 86–3. A paravascular Aschoff's nodule (center of photomicrograph) showing a central area of fibrinoid change and an Aschoff's giant cell surrounded by an edematous intermyocardial connective tissue. (Courtesy of S. Mahfouz, M.D., Pathology Department, Cairo University.)

Fig. 86–4. Unopened heart showing a shaggy, rough, opaque pericardium that is characteristic of rheumatic fibrous pericarditis. Part of the pericardium has been removed showing unremarkable gross changes in the underlying cardiac muscle. (Courtesy of S. Mahfouz, M.D., Pathology Department, Cairo University.)

terstitial myocarditis may be an important factor in the pathogenesis of heart failure during rheumatic activity. This myocarditis is found mainly in the vicinity of the Aschoff's nodules and around blood vessels[68,69] with loss of striations, fatty degeneration, and vacuolation of myocardial cells. Myocytolysis and complete loss of fibers may be seen in some areas.[63]

Endocarditis

Endocarditis affects the mitral and aortic valves and, rarely, the tricuspid or pulmonary valves. In the active phase, the valves become edematous. Endocardial surfaces are damaged along the contact margins 2 or 3 mm from the free edges. At this site, tiny vegetations are formed that consist of platelet thrombi (Fig. 86–5). When inflammation subsides, fibrosis with vascularization and contracture of the leaflets follows. Similar changes affect the chordae tendineae and the annulus. The site of damage at contact points of the cusps suggests that trauma determines the position of the damage. Valve trauma also determines the frequency with which the various valves are involved. The mitral valve, closing at the highest pressure, is subjected to the greatest stress and is therefore the most frequently affected. If inflammation is severe, damage of cusps occurs with development of insufficiency. With milder inflammation, thickening and adhesions take place between the cusps. Adhesions gradually increase with development of stenosis of the valve orifice.

The Conduction System

The high frequency of prolonged P-R interval in acute rheumatic fever is not reflected in pathological changes in the atrioventricular node or bundle of His.[70] The evanescence of atrioventricular block and its reversibility by atropine suggest a functional rather than a structural lesion.

Arteritis of the Coronary Arteries and Other Arteries

The coronary arteries have been well described in rheumatic fever.[70] Coronary arteritis is considered by some to be important

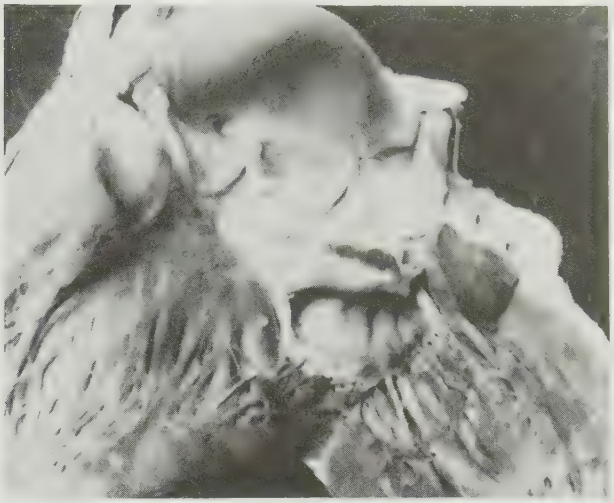

Fig. 86–5. Opened left ventricle displaying both the mitral and aortic valves of a patient with acute rheumatic fever. The mitral valve shows small (1–2 mm) brown, linear vegetations situated on the atrial surface of both anterior and posterior mitral leaflet margins. The aortic valve is grossly unaffected. (Courtesy of S. Mahfouz, M.D., Pathology Department, Cairo University.)

in producing the myocardial damage in rheumatic fever. However, thrombosis of large coronary vessels is very rare.

EXTRACARDIAC PATHOLOGY

Joints

In rheumatic fever there is inflammation, swelling, and edema of the articular and periarticular structures with serous effusion into the joint space. Arthritis of rheumatic fever characteristically heals without residual manifestations because it does not cause erosion of the joint surface or lead to pannus formation.

Subcutaneous Nodules

These resemble Aschoff's nodules but heal rapidly without sequelae. They consist of a central zone of fibrinoid necrotic material surrounded by histiocytes, fibroblasts, and lymphocytes.

Chorea

Because patients with Sydenham's chorea rarely die during the active stage, pathological findings from chorea patients in the central nervous system have not been extensively studied. No characteristic lesion has been found that explains chorea. Perivascular changes in the brains of patients dying of fulminant rheumatic carditis occur whether or not chorea is present.[69]

Pleurisy and Pneumonitis

Pleurisy and pneumonitis may occur with exudative lesions. They only occur with severe carditis and can resemble the lung changes seen with pulmonary infarctions and heart failure. It is not known whether these are primary rheumatic manifestations or secondary to heart failure.

CLINICAL MANIFESTATION

It is important to make the diagnosis of rheumatic fever because subsequent serious cardiac disease can be prevented or minimized by long-term antistreptococcal prophylaxis. Clinical presentation and manifestations are extremely variable. The initial illness may appear acutely with fever and polyarthritis or may be subclinical until mitral stenosis is evident later in adult life. Unfortunately, there is no single clinical sign or laboratory test that is pathognomonic of rheumatic fever.

One typical feature is a latent period between streptococcal infections and RF varying from 7 to 35 days with an average of 18 days.[34] The latent period may be from 2 to 6 months in patients with Sydenham's chorea.[35]

The most commonly used criteria for diagnosis of rheumatic fever are the modified Jones criteria[71] enumerated in Table 86–1. According to these modified criteria, it is mandatory to demonstrate evidence of recent streptococcal infection (usually by elevation of antistreptolysin O titer) and to identify either one major plus two minor criteria or two major criteria. The minor manifestations are less specific for the illness but certainly can indicate the presence of active inflammation in a patient who was previously diagnosed as having rheumatic fever or rheumatic heart disease.

MAJOR CRITERIA

Arthritis

Rheumatic arthritis affects mainly large joints, particularly the knees, ankles, elbows, and wrists. The affected joint is hot, red, and tender. Rheumatic arthritis moves rapidly from one joint to another, resulting in the typical picture of a migratory polyarthritis. Each joint usually remains inflamed for no more than a week before inflammation starts to subside. It is important to withhold antiinflammatory agents until signs and symptoms are sufficient for the recognition of migratory polyarthritis if the diagnosis is uncertain.

Polyarthritis occurs in about 75% of patients during the acute stage of the disease. Joint involvement is more common in older patients. Joint involvement is accompanied by a lower incidence of carditis and chorea.[72,73]

Table 86–1. Modified Jones Criteria for Diagnosis of Rheumatic Fever

Requirement for Diagnosis	*Major Criteria*
a) Two major criteria or	Carditis
b) One major plus two	Arthritis
minor criteria	Chorea
	Erythema marginatum
	Subcutaneous nodules
c) Plus evidence of previous	*Minor Criteria*
streptococcal infection:	
* Recent scarlet fever or	Previous rheumatic fever
* Raised antistreptolysin O	Arthralgia
(ASO) titre or	Fever
* Positive throat culture	Acute phase reactants
	First-degree atrioventricular block

Rheumatic polyarthritis characteristically responds to salicylates. Joints are left without any sequelae except for the very rare (Jaccoud's type) of deformity of the metacarpophalangeal joints.[73,74] This is a result of periarticular fibrosis rather than synovitis.

Acute polyarthritis is almost always associated with a high or rising titer or streptococcal antibodies. Arthritis usually occurs within 30 days after the onset of streptococcal infection, when the antibody titer is at maximum.

Carditis

Carditis is the most serious major manifestation of rheumatic fever, since it may cause acute heart failure or culminate in chronic valvular heart disease.

The incidence of clinically evident carditis in the initial attack of rheumatic fever varies from 40 to 50%.[75] Carditis in its most severe form is rare in the current era but can lead to heart failure and death. Usually, carditis causes no symptoms and is diagnosed during examination of the heart of a patient who has arthritis or chorea. If other symptoms of rheumatic fever are absent or if carditis is mild, carditis might not even come to medical attention during the acute stage. This fact accounts for patients who have rheumatic heart disease without a history of rheumatic fever. One common presentation, particularly in children, is an insidious form with low-grade or no fever, with vague or absent arthritis or arthralgia, but with severe cardiac involvement. Carditis with *recurrent* rheumatic fever may present as congestive heart failure in a patient with rheumatic heart disease who was previously compensated.

Residual valvular disease depends on the severity of the initial episode of carditis and on the subsequent prevention of recurrent rheumatic fever. In one long-term study,[76] the incidence of residual valvular heart disease was almost 0% in patients without evidence of carditis in the first episode of rheumatic fever as long as recurrences were prevented.

Patients with carditis in the initial episode of rheumatic fever usually develop residual rheumatic heart disease. If recurrences can be prevented, the long-term outcome is better. Carditis is more apt to recur if rheumatic fever occurs in patients who have had carditis in the initial attack, thus increasing the risk of severe residual heart disease.[77] Rheumatic carditis may be found to have clinical features of involvement of the endocardium (including the valves), myocardium, or pericardium but frequently a combination of all three. The unequivocal signs of carditis in a patient with rheumatic fever are (1) an organic heart murmur that was not previously present, (2) pericardial friction rub or effusion, and/or (3) cardiac enlargement with or without heart failure.

Valvulitis

Mitral Valvulitis. The mitral valve is the most common site of inflammation in the course of rheumatic fever. It is affected almost three times more frequently than the aortic valve.[78] It can be diagnosed by:

1. The development of a loud apical systolic murmur that radiates to the axilla accompanied by a muffled first sound and a third sound caused by the development of mitral insufficiency. A systolic murmur over the apex without these characteristics may be an innocent murmur or caused by the fever and not mitral valvulitis.
2. The occurrence of a mid-diastolic murmur over the apex

resulting from narrowing of the mitral orifice by the thickened edematous cusps. The murmur begins after a third sound and is low pitched and localized to the apex.[79] This murmur implies definite mitral valvulitis. This was the murmur described by Carey-Coombs. The term "Carey-Coombs" murmur has come to mean the diastolic murmur associated with mitral regurgitation of any cause. The murmur may persist, indicating permanent damage, but it frequently disappears for a variable time to develop later—because of development of adhesions between the valve cusps—as the diastolic murmur of mitral stenosis.

Aortic Valvulitis. Aortic valvulitis may occur alone or with mitral valvulitis and can be diagnosed by:

1. The occurrence of an early diastolic murmur over the base. The murmur is a soft, high-pitched decrescendo murmur heard immediately after the second heart sound. The murmur may appear early in the course of the disease and is a definite sign of aortic valvulitis. A wide pulse pressure characteristic of aortic insufficiency can be noted early in the course of rheumatic fever.
2. As in mitral valvulitis, a systolic murmur over the base occurs either from the fever or from aortic valvulitis. It is not as predictive a sign as is the diastolic murmur. The murmurs of mitral and aortic valvulitis may disappear or may be followed by the establishment of chronic valve regurgitation, stenosis, or both, according to the pathological process occurring in the valve. Regurgitation of the mitral or aortic valves, being caused by damage to the valve, takes a short time to develop. Stenosis of these valves resulting from union of mobile cusps takes a longer time to develop.

Myocarditis

Myocarditis is usually accompanied by valvulitis and leads to:

1. Tachycardia (out of proportion to the fever) that persists during sleep.
2. Rapid cardiac enlargement, particularly involving the left ventricle and left atrium.
3. Heart failure. Congestive heart failure is a serious complication of rheumatic fever and indicates significant myocarditis. It occurs in 5 to 10% of first attacks, but it is more common as a manifestation of recurrence. Shortness of breath, tachycardia, and gallop are important early signs of left ventricular failure. Unexpected weight gain, engorgement of neck veins, and enlargement of the liver are early signs of right ventricular failure. A chest roentgenogram might be very helpful in the diagnosis of incipient heart failure, and echocardiography might reveal evidence of myocardial dysfunction.

One must occasionally differentiate between tachypnea resulting from salicylism from that resulting from heart failure. A "gallop rhythm" should not be diagnosed unless there are other signs of carditis. Children with rheumatic fever frequently have a prominent third sound as well as tachycardia.

Pericarditis

Pericarditis, which may be dry or with mild effusion, is encountered in only 5 to 10% of patients with carditis.[74,80] The degree of pericarditis does not correlate with the degree of myocarditis. A pericardial friction rub is pathognomonic. The rub may be heard widely over the precordium or localized to a single area. Murmurs of valvulitis are usually heard in the patient who develops pericarditis. The pericardial friction rub may be so loud that cardiac murmurs are obscured. S-T segment elevation in the electrocardiogram is unusual. Echocardiography can be useful in detecting even small pericardial effusions.

Chorea

Rheumatic or Sydenham's chorea (St. Vitus' dance) is more common in females. This usually occurs without carditis or polyarthritis. Chorea has decreased in frequency in comparison with arthritis and carditis.

The onset is usually gradual. Emotional instability is often a prominent feature. Many children who have chorea are labeled as having behavioral problems until the problem is recognized.

There are involuntary, uncoordinated, purposeless jerky movements. The patient, after protruding the tongue for inspection, may withdraw it rapidly, snapping the jaws. Speech is usually indistinct. The hand grip is often unsustained and is known as the "milkmaid's hand." Flexion at the wrists and dorsiflexion of the finger occur in the outstretched hands, giving the appearance of the "silver fork" deformity caused by hypotonia. Objects are often dropped from the hands. Excitement, fatigue, and effort increase the movements; sleep causes them to disappear. Handwriting is particularly affected. Serial evaluation of the patient's handwriting is an objective way of following improvement.

The latent period for chorea after streptococcal pharyngitis is from 1 to 6 months.[81] As a result, by the time chorea is manifest, streptococcal antibodies and acute phase reactants are normal.

Chorea is a self-limiting disease. It lasts an average of 3 months but may last for as long as 6 to 12 months. A 30-year followup of a group of patients with rheumatic chorea revealed that 27% of these patients developed rheumatic heart disease.[82]

Subcutaneous Nodules

Subcutaneous nodules, a rare major criterion of rheumatic fever, occur with severe carditis.[83] The nodules vary in size from 0.5 to 2 cm and are attached to the tendon sheaths. They occur on the extensor surfaces of bony prominences, scapulae, and mastoid processes. They consist of a collection of Aschoff bodies but are evanescent.

Subcutaneous nodules are not pathognomonic of rheumatic fever, since they occur in rheumatoid arthritis and systemic lupus erythematosus.

Erythema Marginatum

Erythema marginatum is also very rarely seen today. Initially, there is an area of erythema with advancing margins that clears in the center (Fig. 86–6). This lesion is painless and not pruritic. Erythema marginatum is transient and is found chiefly over the trunk and inner aspects of the arms and thighs. The rash blanches on pressure.

Like subcutaneous nodules, erythema marginatum is a major manifestation of rheumatic fever, but it is not pathognomonic, having also been reported in drug reactions and glomerulonephritis.[84]

MINOR CRITERIA

The minor manifestations occur regularly in rheumatic fever. Because they are common to many inflammatory diseases, they

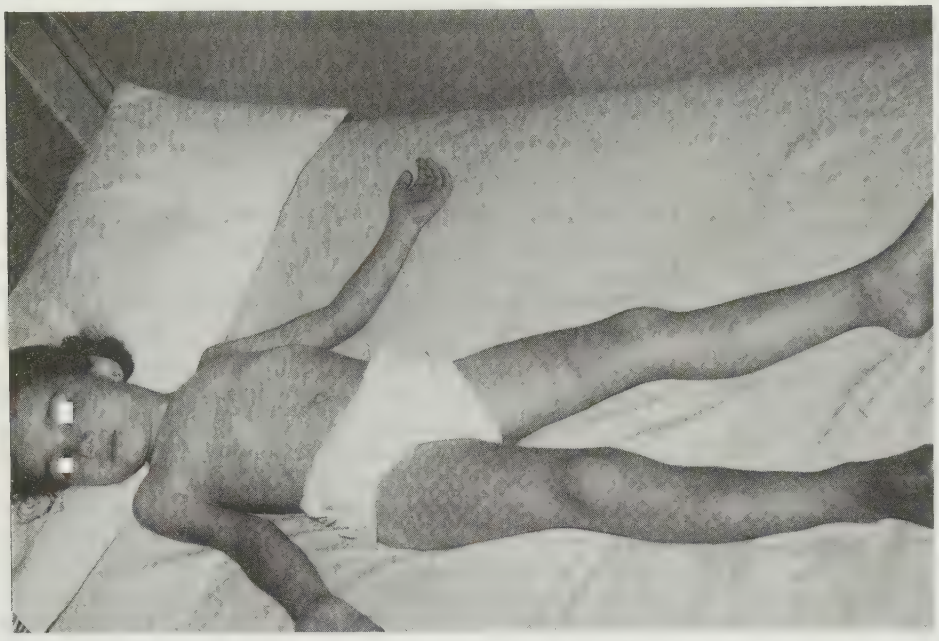

Fig. 86–6. A 6-year-old girl with erythema marginatum who had acute rheumatic fever with severe carditis. (Courtesy of Professor Samir Kassem, M.D., Alexandria Medical School.)

are of minor diagnostic value. They are helpful in diagnosing recurrent rheumatic activity in a patient who has already been diagnosed as having rheumatic heart disease. The minor criteria are listed in Table 86–1.

Fever

In the classical form, which is very rare nowadays, rheumatic fever starts with a fever between 100 and 104°F, which decreases in a few days to become low-grade or disappear. However, more often recorded is a low-grade fever from the start that might be found only in the afternoon. Rheumatic fever should not be diagnosed only on the basis of a prolonged fever unless there are other signs of the disease.

Arthralgia

Arthralgia in the form of dull, aching pains around the joints without objective findings is frequently noticed, particularly in patients with carditis. Arthralgia cannot be used as a minor criterion for diagnosis in patients with arthritis.

Abdominal Pains

Abdominal pains may occur early in the course of the disease even before arthritis. These pains may simulate acute appendicitis.[85] This pain is thought to be caused by vasculitis. Abdominal pain in rheumatic fever may also be epigastric from pericarditis, right hypochondrial from liver congestion, or caused by gastritis as a result of steroids or aspirin.

Pneumonia

Rheumatic pneumonia is rare and usually occurs with severe carditis. The pneumonia is characterized by marked tachypnea with little or absent rales. The chest roentgenogram shows a rapidly changing pattern that is suggestive of pulmonary edema migrating from one area of the lung to another.

Electrocardiogram

Long PR intervals are found commonly in acute RF but may be found in many other settings.

Laboratory Evidence Indicating Acute Infection

Laboratory evidence does not come from specific tests but is very important, since it indicates active disease. It includes elevated leukocyte count, high erythrocyte sedimentation rate, and presence of C-reactive protein.

Erythrocyte Sedimentation Rate

With the exception of established chorea, erythrocyte sedimentation rate is almost always elevated above 60 in the early part of the disease. Congestive heart failure may lower ESR, but not to normal levels. The ESR remains elevated for 6 to 12 weeks in untreated patients. Anti-inflammatory agents suppress the ESR coincident with suppression of the clinical signs of inflammation. Sometimes the ESR may remain moderately elevated without any other evidence of inflammatory activity.[86]

C-Reactive Protein

Like the ESR, C-reactive protein (CRP) rises in the acute phase of rheumatic fever and is not a specific test.

Complete Blood Count

A complete blood count usually demonstrates a moderate anemia, partly caused by increased plasma volume and decreased erythropoiesis.[79] Leukocyte count is increased to a moderate degree.

Serum Proteins

Like ESR, serum gamma globulins are usually elevated but are not a specific indication of rheumatic fever. Immunoglobulin A is also elevated, while immunoglobulin M is infrequently so.[87] A significant elevation of alpha macroglobulins (e.g., ceruloplasmin)

can be found in the early phase of rheumatic fever and falls toward normal, paralleling ESR.[88]

Evidence of Previous Streptococcal Infection

Streptococcal Antibodies

Specific antibody tests are generally reliable methods of obtaining evidence of recent streptococcal infection. Titers obtained with these specific antibody tests may be elevated even in the absence of clinical or current bacteriologic evidence of streptococcal disease. Antibody responses may be suppressed by antibiotic therapy and may be suppressed or delayed by steroid therapy.

Antibodies used to diagnose antecedent streptococcal infection have included antistreptolysin O (ASO), antideoxyribonuclease-B, antistreptodornase, antidiphosphopyridine nucleotidase (anti-DPNase), antistreptokinase, antihyaluronidase, and antistreptococcal esterase.

The antistreptolysin O antibody is abnormally elevated in 70 to 85% of patients with acute RF. A single value of 500 units is considered indicative of recent streptococcal infection, and a value of 333 units is of borderline significance. If antistreptolysin O titer is 333 or less, additional antistreptococcal antibody assays should be obtained. These include antideoxyribonuclease-B (antistreptodornase),[88] antidiphosphopyridine nucleotidase (anti-DPNase),[89] antihyalurinidase, antistreptococcal esterase,[69] and antistreptokinase.[90] When three different streptococcal antibodies are measured, more than 95% of patients with acute RF have abnormal elevation of at least one of them. The streptozyme test[91,92] includes an assay for antibodies against five extracellular antigens of Group A streptococci (streptolysin O, hyaluronidase, streptokinase, deoxyribonuclease B, and nicotinamide adenine dinucleotidase). Unfortunately, false positive streptozyme tests are common,[93] and we do not recommend the use of the streptozyme test alone as a screening test. The streptozyme test is useful in conjunction with a negative or borderline antistreptolysin O titer. A negative streptozyme test with a negative or borderline antistreptolysin O titer indicates that recent streptococcal infection is unlikely.

These antistreptococcal antibody tests are specific only for streptococcal infection and not for acute rheumatic fever. The major contribution of these tests is to provide assurance that the disease entity under consideration has been preceded by an illness that could have resulted in rheumatic fever. Some authors[94] have recommended testing three antibodies (e.g., ASO, ASKase, and ADNase-B) at a time. If two of the three titers are positive, one can make the diagnosis of fairly recent streptococcal infection. If only one of the three titers is positive, previous or nonspecific causes of the antibody rise should be considered.

The determination of antibodies to the group A carbohydrate (A-CHO) moiety of the streptococcal cell wall has not been selectively helpful in the diagnosis of acute rheumatic fever. However, because antibodies to group A carbohydrate remain for several years in patients with persistent rheumatic valvular disease, this test could aid in the differentiation of rheumatic from nonrheumatic heart disease.[87,95]

Throat Culture

A throat culture is of little practical value. Since there is usually a latent period of 1 to 3 weeks between pharyngitis and the appearance of rheumatic fever, a throat culture taken at the onset of rheumatic fever is frequently negative. A throat culture that shows streptococci does not prove recent infection, since children can be streptococcal carriers.

History of Scarlet Fever

When present, scarlet fever is usually a reliable indicator of preceding streptococcal infection.

THE CHANGING PICTURE OF RHEUMATIC FEVER

Over the years, there have been changes not only in the occurrence of rheumatic fever but also in its severity, presentation, clinical manifestations, and possibly cause.

Several reports have described the virtual disappearance of rheumatic fever in different areas of the United States.[96,97] However, there are differences among reports[98,99] as to whether these trends apply to all racial, socioeconomic, and geographic subgroups. Most studies have indicated a higher incidence of rheumatic fever in blacks, native Americans, and the poor. A review[100] of mortality and morbidity statistics of the U.S. National Center for Health Statistics showed that similar changes have occurred nationwide for acute rheumatic fever but not for chronic rheumatic heart disease, which still causes considerable mortality, morbidity, and utilization of costly surgical facilities. The age-adjusted mortality rate per 100,000 for the combined category of rheumatic fever and rheumatic heart disease has declined in the United States from 14 in 1950 to 2.2 in 1982. In 1982, however, an outbreak of rheumatic fever was noted in the intermountain area of the western United States with an eightfold increase over the average annual incidence from the same area.[6] In developing countries, rheumatic fever and rheumatic heart disease remain a major public health problem.[101,102] A recent large survey in India found that between 200 and 1200 children per 100,000 are afflicted with rheumatic fever annually.

Not only is the occurrence of rheumatic fever less in developed countries, but when it occurs, it tends to be mild. In many tropical and subtropical less developed countries, chronic rheumatic heart sequelae are not only common but assume a malignant form (Figs. 86–7 to 86–10). Many of these patients have severe pulmonary hypertension[103] and require surgery at a young age.

In areas where rheumatic fever is still common, it has been noted that the disease runs a subacute rather than an acute course. Joint involvement is less conspicuous. Rheumatic nodules and erythema marginatum are becoming very rare, but chorea is still seen. Chronic active forms are common; the acuteness of the symptoms has subsided, but the severity of cardiac process has not ameliorated. This is in contrast to the European and U.S. experience, in which both the acuteness and severity of rheumatic fever have decreased.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis of rheumatic fever is not an easy task today, except in florid, clear-cut cases. The Jones criteria and the revised modification two decades later leave much to be desired.[104,105] The criteria are not sensitive enough to include mild cases and not sufficiently specific, since other conditions may be wrongly diagnosed as rheumatic fever. As a result, both overdiagnosis and

Fig. 86–7. A young, underdeveloped Egyptian female, 11 years old, with recurrent rheumatic fever on top of mitral and aortic rheumatic valve disease. This is a common problem in many developing nations where rheumatic fever and multivalvular heart disease with gross cardiomegaly is seen at such a young age.

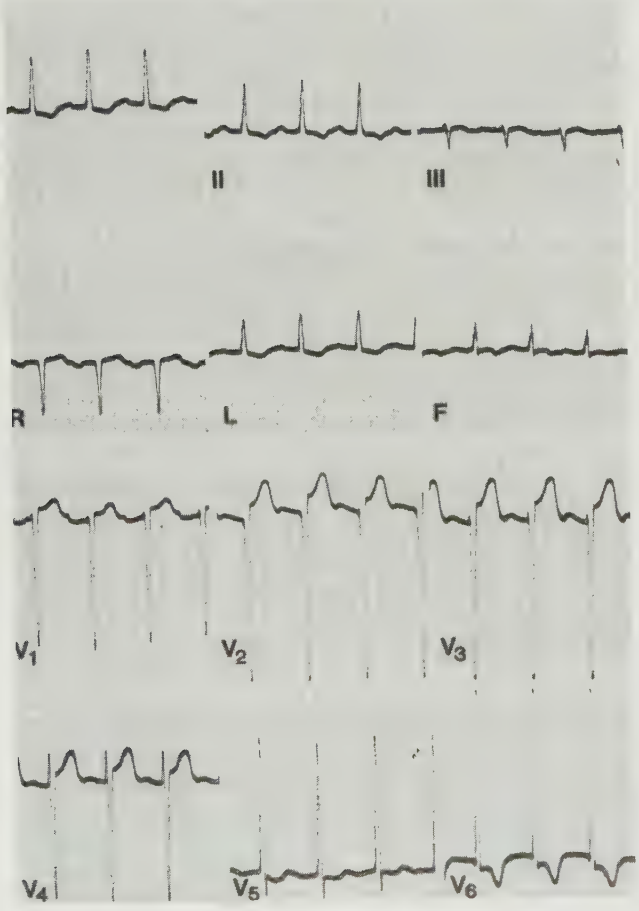

Fig. 86–8. The electrocardiogram of the patient of Fig. 86–7 showing sinus tachycardia, a prolonged P-R interval, left ventricular hypertrophy, and strain.

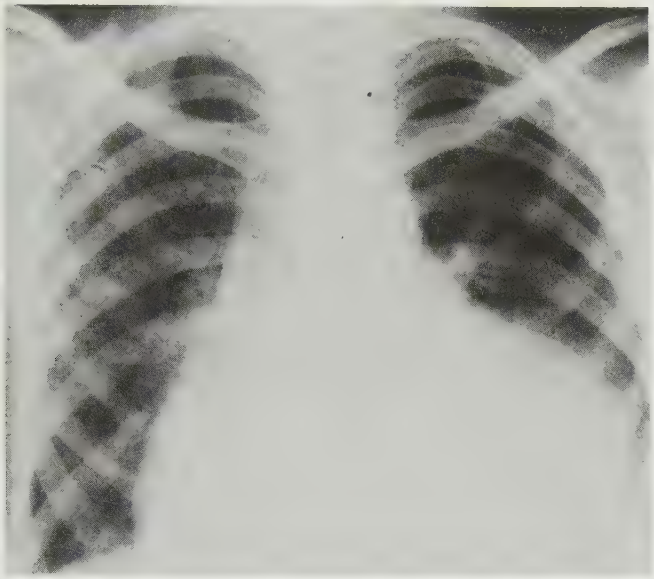

Fig. 86–9. Posteroanterior chest roentgenogram of the patient of Fig. 86–7 depicting gross cardiomegaly.

underdiagnosis occur. This fact should be taken into consideration in examining a patient who is suspected of having rheumatic fever.

Fever and Arthritis

Fever and arthritis must be differentiated from other causes of polyarthritis in children.

Juvenile Rheumatoid Arthritis

Rheumatoid arthritis in its early phase, when it involves big joints, may be difficult to differentiate from rheumatic polyarthritis. The points in favor of rheumatoid arthritis rather than rheumatic fever include involvement of small joints, particularly the hands and feet; morning stiffness; fusiform swelling of fingers and joint deformities; lymphadenopathy; splenomegaly; and absence of antistreptococcal antibodies.

Infective Endocarditis

Unexplained fever and arthralgia in a patient with rheumatic heart disease may be rheumatic reactivation or infective endocarditis. The points in favor of infective endocarditis would include petechiae, hematuria, clubbing, splenic enlargement, embolic findings, and positive blood culture.

Sickle Cell Anemia

In sickle cell anemia, which is caused by microvascular thrombosis, there may be manifestations like those of rheumatic fever such as joint pains, fever, heart murmurs, cardiac enlargement, and abdominal pain. Hemoglobin electrophoresis is diagnostic.

Polyarthritis

Polyarthritis occasionally is seen with bacterial infections such as pneumococcal, gonococcal, meningococcal, and staphylococcal infections. These can usually be diagnosed by blood or joint cultures. Osteomyelitis might simulate rheumatic fever if pain is referred to a big joint.

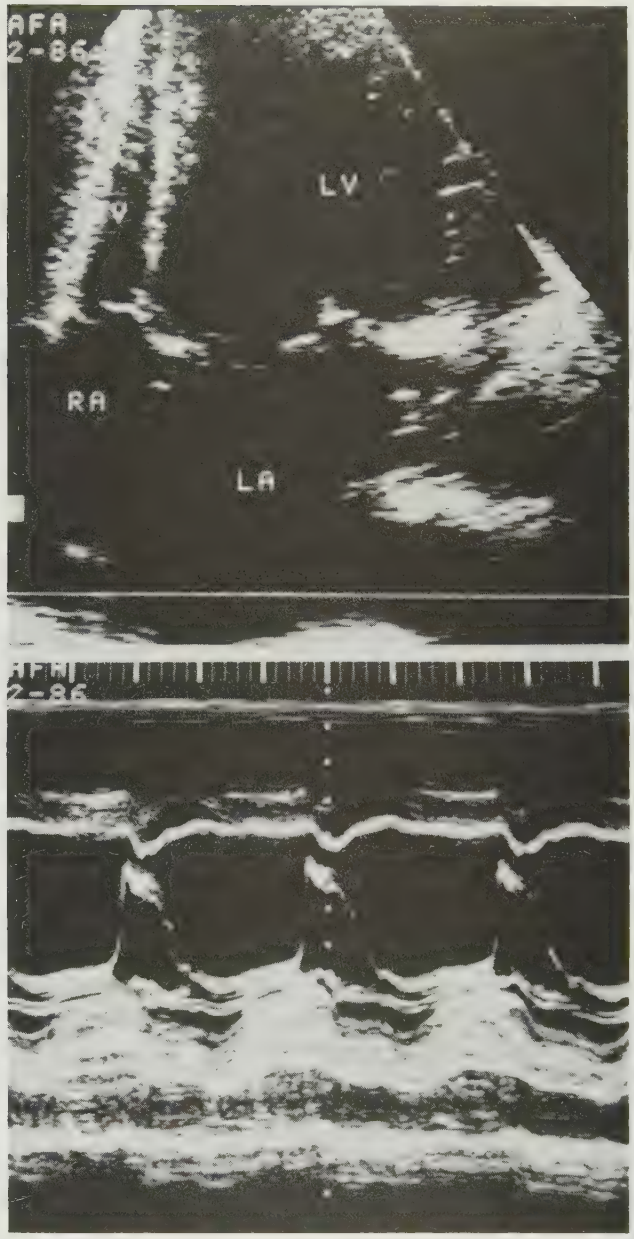

Fig. 86–10. Two-dimensional and M-mode echocardiograms of the patient of Fig. 86–7. (top) Apical four-chamber view showing a dilated left ventricle and left atrium and thickened mitral valve. (bottom) M-mode echocardiogram at the level of the mitral valve showing thickened mitral valve and pericardial effusion.

Immune Complex Disease

Immune complex disease may also resemble rheumatic fever. A notable example is serum sickness.

Carditis

The heart murmurs of rheumatic fever must be differentiated from functional murmurs, mitral valve prolapse, myocarditis, pericarditis and congenital heart disease.

Functional Murmurs

Functional murmurs may create confusion. Fever increases the intensity of the functional murmur.

Myocarditis

Viral and other forms of myocarditis may be difficult to differentiate from rheumatic fever, especially if the extracardiac manifestations of rheumatic fever are absent. Myocardial biopsy might be helpful.

Pericarditis

Primary viral pericarditis may be confused with an early case of rheumatic fever,[106] but the appearance of other manifestations of rheumatic fever and antistreptococcal antibodies are of great help in differentiation.

Mitral Valve Prolapse

Mitral valve prolapse and congenital anomalies affecting the mitral valve may at times create problems. The murmur of mitral prolapse increases with fever and can be confused with mitral valvulitis. The absence of other manifestations of rheumatic fever and high antistreptococcal titers help in differentiation. The echocardiogram is also characteristic. It has been suspected, however, that rheumatic mitral involvement may be a cause of mitral valve prolapse.

COURSE AND PROGNOSIS

The clinical course of patients with rheumatic fever is extremely variable, but there is usually a characteristic sequence and predictable duration for the major manifestations.

The onset of disease is usually abrupt in patients whose initial manifestations are fever and arthritis. The disease begins much more insidiously in patients presenting with Sydenham's chorea. Carditis also may be subtle in its appearance and may be unsuspected until a murmur is heard on physical examination.

The presence or absence of carditis is an important determinant of the course and prognosis of acute rheumatic fever. The incidence of carditis depends on age. In one study, before the age of 3 years, 90% of patients had carditis.[101] The incidence of carditis decreased to 50% in the 3- to 6-year-old age group, and to 32% in the 14- to 17-year-old age group.[107] After the age of 25, carditis was very rare with the first attack of rheumatic fever. The duration of rheumatic activity is longer in patients with carditis than those without cardiac involvement.[108] The usual duration is rarely longer than 3 months even when severe carditis is present. In fewer than 5% of patients, rheumatic fever may remain active for more than 6 months.[86] These patients are considered to have a state of chronic active carditis.

The prognosis is excellent for subjects who escape carditis during an initial attack of rheumatic fever.[74,109] The prognosis worsens with increasing severity of initial carditis and with recurrences.

The mean duration of rheumatic activity is shortest when no suppressive drugs are given.[108] Rheumatic activity appears to be prolonged when rebounds of activity occur after withdrawal of antirheumatic drugs. Suppressive therapy masks the inflammation but does not terminate the process and may actually prolong it.

RECURRENCE OF RHEUMATIC FEVER

First attacks of rheumatic fever in the general population following epidemic streptococcal pharyngitis average 3%. Such infections in patients with a history of previous but recent rheumatic fever may produce a secondary attack rate as high as 65%.[11] The rheumatic attack rate decreases with the passage of time[103] to reach about 4 to 8% ten or more years after the last attack. Another factor that increases the chance that a second streptococcal infection will be followed by a rheumatic attack is the presence of residual valvular heart disease.[50]

Any patients with rheumatic valvular disease and a fever of unknown cause should be suspected of recurrent rheumatic activity, especially if there is evidence of streptococcal infection.

TREATMENT

Prophylactic

The most effective preventive measures against rheumatic fever are socioeconomic and sanitary. Adequate housing and relief of crowding are important in prevention of streptococcal infections.

Primary Prophylaxis

The aim of primary prophylaxis is to prevent the initial attacks of rheumatic fever by identification and treatment of the streptococcal pharyngitis. Effective prevention demands the eradication of the infecting organism. A single intramuscular injection of benzathine penicillin (600,000 units in children under 25 kg and 1.2 million units in those over 25 kg) is the most effective method.[110] This is preferred to oral penicillin, which requires 10 successive days of treatment. For patients who are allergic to penicillin, erythromycin (25 mg/kg/day) is given for 10 days. Primary prophylaxis proved to be very effective in military populations with a high frequency of streptococcal infections, with a reduction of the attack rate of rheumatic fever from 3% to 0.3%.[111]

Mass antibiotic prophylaxis by intramuscular administration of 1.2 million units of benzathine penicillin to all members of an affected population has been effective.[112–114] This approach can be applied if possible in civilian epidemics. On the other hand, with the marked decline in streptococcal pharyngitis and rheumatic fever in many populations, the need for treatment of simple pharyngitis with penicillin has been questioned. In these populations, selective throat cultures for beta-hemolytic streptococci should be made. A negative culture makes antibiotic therapy of simple sore throat unnecessary more than 95% of the time.[115]

At present, there is no effective vaccine against streptococcal infections for general use, although one is under investigation.[116] The clinical and epidemiologic efficacy of a streptococcal vaccine has not been conclusively demonstrated. Recent studies have suggested that it might be possible to induce antibodies with small doses of purified M-protein.[117] Recent advances in the purification of M-proteins and definition of their molecular structure have provided encouraging data that could ultimately make the approach to a group A streptococcal vaccine more feasible.[19,118]

Secondary Prophylaxis

Secondary prophylaxis is the prevention of recurrences of rheumatic fever by continuous chemoprophylaxis. The most effective has been a single monthly intramuscular injection of 1.2 million units of benzathine penicillin.[119] Oral penicillin prophylaxis consists of 500 to 1000 mg of penicillin twice daily. If the patient is allergic to penicillin, chemoprophylaxis can be achieved with 250

mg of erythromycin twice daily. Oral sulfonamide prophylaxis is no longer used because of side-effects and the appearance of resistant streptococcal strains.

The injectable form of prophylaxis is more effective than the oral form. In the Irvington house study, the attack rate with the injectable form of prophylaxis was one recurrence per 250 patient years compared with ten recurrences per 250 patient years with oral prophylaxis.[111] Allergic reactions with the injectable forms are more serious than with the oral penicillin, but such reactions are extremely rare after the first months of prophylaxis. There is considerable controversy about duration of prophylaxis. The American Heart Association recommends prophylaxis for life. In Egypt, we administer prophylaxis until the patient is 25 years old or for 10 years after the last rheumatic fever attack.

Tonsillectomy was at one time almost a routine procedure in rheumatic subjects. Although there is some evidence that tonsillectomy may reduce the frequency of clinically apparent streptococcal infection and large tonsils are associated with increased frequency of recurrences in rheumatics with poor prophylactic compliance, there is no evidence that tonsillectomy reduces the attack rate of rheumatic fever.[120]

Treatment of Acute Rheumatic Fever

Rest

Patients with rheumatic fever must remain in bed during the acute and febrile portion of the illness. Light physical activity can be allowed once the acute febrile illness has abated and signs of carditis have stabilized. Children with polyarthritis alone can usually go to school in 4 to 6 weeks following the onset of symptoms. Patients with carditis should have rest until signs of cardiac inflammation subside. Strenuous activity and physical exercise are not allowed in any patient before 2 to 3 months.

Diet

No special diet is necessary unless heart failure is evident, in which case salt should be restricted.

Penicillin

Once the diagnosis has been made, a course of penicillin adequate to eradicate residual group A streptococci must be given even if a throat culture is negative. A single injection of 1.2 million units of long-acting penicillin is adequate. Secondary prophylaxis must start immediately.

Anti-inflammatory Agents

The administration of these agents should be delayed until a proper clinical and laboratory diagnosis has been established. Premature administration of these agents to a patient with arthralgia or early monoarticular arthritis might mask the disease process and cause diagnostic confusion.[108]

The antirheumatic agents used, whether salicylates or corticosteroids, are valuable symptomatic and supportive drugs. However, they are not curative and might actually prolong the course of the disease. The outcome of rheumatic fever has not been affected by the antirheumatic agent selected.[74,109,121]

Aspirin. Acetyl salicytic acid (aspirin) is analgesic and antipyretic and generally makes the patient feel better. It causes dramatic improvement of the arthritis to the extent that it can be given as a therapeutic test, but it is without effect on carditis.

Indications: Aspirin is given to patients without carditis if there are side-effects or contraindications to the use of corticosteroids and during and after withdrawal of corticosteroids.

Toxicity: Side-effects of aspirin include tinnitus, gastric irritation, bleeding tendency, metabolic acidosis, hyperventilation and respiratory alkalosis, idiosyncrasy, and hypoglycemia.

Dosage: The usual dose is 90 to 120 mg/kg (one grain per pound) body weight/day divided into every four-hour interval doses until a satisfactory clinical response is obtained. A serum salicylate level between 15 and 25 mg/100 mL gives optimal therapeutic effect. The dose is then reduced to two thirds and continued until inflammation subsides clinically (or, according to some practitioners, until all laboratory manifestations are normalized). This usually takes 6 to 9 weeks. After this, the dose is gradually decreased to avoid the rebound that occurs if the drug is stopped abruptly.

Corticosteroids. Neither salicylates nor corticosteroids guarantee termination of the disease and its cardiac damage. However, steroids result in more prompt resolution of the inflammatory process than aspirin and so can decrease the load on the heart.[107,121,122]

Indications: Corticosteroids are indicated for patients with moderate carditis if the disease is not adequately suppressed by salicylates or if salicylates are not tolerated.

Dosage: The usual dose is 2 mg/kg/day of prednisone or prednisolone, not to exceed 60 mg/day for 3 to 4 weeks.

Many controlled studies have been done comparing aspirin with corticosteroids. Some support the use of steroids,[122,123] and others did not find any benefit.[109,124] At present, no firm conclusions about the place of steroids in preventing the development of rheumatic heart disease can be reached. In most cases, carditis appears early in the course of rheumatic fever,[102] and regardless of treatment, the risk of developing subsequent heart disease is probably minimal in patients who do not have carditis at the time of admission to the hospital or at the time treatment is begun.[122] It seems reasonable to limit consideration of the use of steroids to patients who exhibit carditis of at least moderate degree, especially those with evidence of heart failure. Patients who have arthritic disease alone or who have only mild or questionable carditis can usually be treated well with aspirin.

Treatment of Chorea

Patients must be cared for in a quiet environment protected against self-inflicted injury caused by uncontrollable movements. Chlorpromazine or diazepam[125] can be used as sedatives. Barbiturates may cause agitation. Haloperidol (butyrophenone) is the most effective drug in controlling the abnormal movements, but extrapyramidal reactions have been reported.[126] Patients with concomitant rheumatic activity can be given aspirin, and those with carditis may receive steroids. There is no definitively known value of steroids or aspirin on the course of chorea itself.

Treatment of Heart Failure

Heart failure, if present, is treated in the usual ways with diuretic therapy and digitalis.

Surgical Treatment

Surgical treatment is resorted to rarely as a life-saving measure if there is gross mitral and/or aortic valve insufficiency and the patient is not improving on vigorous medical treatment.

Plasmapheresis

Since rheumatic fever patients have circulating immune complexes in their blood that might be the cause of the cardiac damage, plasmapheresis has been reported in three cases of rheumatic fever with improvement of abnormal clinical and laboratory findings as well as marked reduction of the high levels of circulating immune complexes.[126]

CHAPTER 87

Rheumatic Heart Disease

Galal M El-Said
Medhat M El-Refaee

Chronic rheumatic heart disease, like rheumatic fever, is most common in areas where the standard of living is low. The decline in the frequency and severity of rheumatic heart disease in Western Europe and the United States, which started even before antibiotics became available, is attributed mainly to improved socioeconomic standards.[1] Rheumatic heart disease is still one of the most important causes of heart disease in less developed areas. It constitutes 25 to 40% of government general hospital cardiac admissions in India, Egypt, Thailand, the Philippines, Jamaica, and Puerto Rico. In these areas, rheumatic fever and its recurrences are not only common but also assume a malignant form, leading to well-established and significant valvular heart disease in children, often with pulmonary hypertension.[2] Many of these patients either need surgery or succumb before the age of 20. In children and adolescents, the mitral valve is involved in 85% of cases, the aortic valve in 54%, and the tricuspid and pulmonary valves in less than 5%.[3]

RHEUMATIC MITRAL INSUFFICIENCY

Healing of acute rheumatic mitral valvulitis may cause mitral insufficiency and/or stenosis, depending in part on the resultant physical orientation of the mitral leaflets. Mitral regurgitation is the most common chronic rheumatic heart disease in children and adolescents. Mitral stenosis is usually associated with mitral regurgitation. Mitral insufficiency results from fibrosis and contracture of the valve leaflets so that they cannot efficiently coapt.[3] The severity of the lesion is variable. In patients with severe mitral regurgitation, there is disorganization of the valve mechanism and shortening of the valve cusps, chordae tendineae, and papillary muscles (Fig. 87–1). In advanced and long-standing cases, the inflamed leaflets calcify. Calcification may extend from one leaflet to the other across one or both commissures, keeping the two leaflets apart at the involved commissure. As the left atrium enlarges from the insufficiency, it displaces the posterior leaflet posteriorly, while it is restrained at the opposite end by its tensor apparatus. The result is that the posterior leaflet may lose its capability to move. The increase in mitral insufficiency initiates a vicious circle wherein "mitral insufficiency begets mitral insufficiency."[4]

Pathophysiology

As the left ventricle contracts, part of its stroke volume regurgitates to the left atrium through the incompetent mitral valve. Because of the pressure difference between the left ventricle and the left atrium, regurgitation starts during the phase of isometric contraction of the left ventricle, and almost half of the regurgitant volume is ejected into the left atrium before the aortic valve opens.[5] The volume of regurgitation depends on the size of the regurgitant orifice as well as on the pressure gradient between the left ventricle and the left atrium.[6] The amount of left ventricular stroke volume ejected into the left atrium influences the degree of left atrial enlargement as well as left ventricular dilatation.[7] The systolic regurgitant flow produces the characteristic prominent v wave in the left atrium. The increased diastolic transmitral volume flow produced by the blood that leaked during the previous systole in addition to the pulmonary venous return produces a flow murmur that can mimic mitral stenosis (Carey Coombs murmur, in conventional usage).

Fig. 87–1. Opened specimen showing severe rheumatic mitral insufficiency. The leaflets, chordae tendineae, and papillary muscles are fibrosed and retracted. The left ventricle is dilated. (Courtesy of Dr. Soheir Mahfouz, Pathology Dept., Cairo University.)

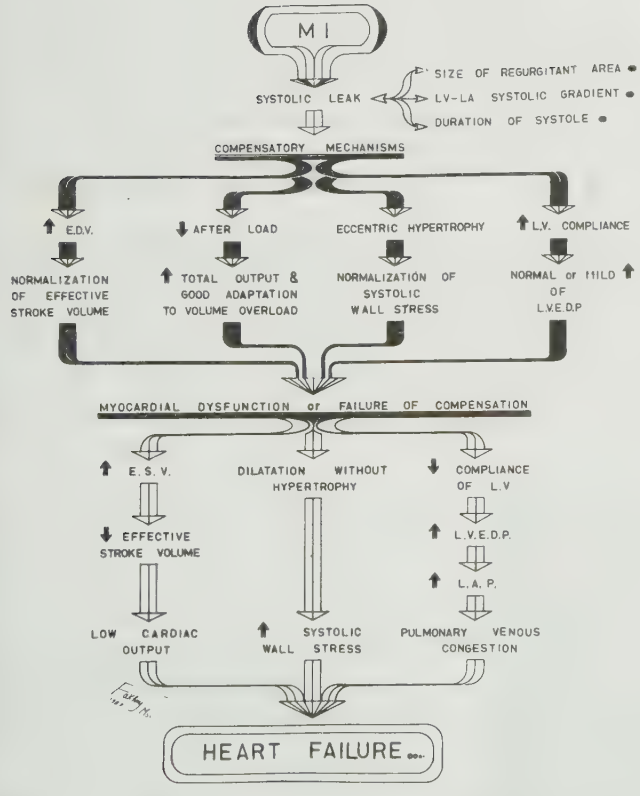

Fig. 87–2. A diagram depicting factors that determine the degree of regurgitation, compensation, and decompensation in mitral insufficiency.

Compensation in chronic mitral insufficiency (Fig. 87–2) includes dilatation of the left ventricle to accommodate the increased filling volume. The increase in left ventricular end-diastolic volume permits a large stroke output. This maintains forward systemic flow. The increase in left ventricular end-diastolic fiber length is not initially reflected in an increase in end-diastolic pressure because of the increase of left ventricular distensibility (compliance). An increase in left ventricular as well as left atrial compliance in chronic mitral insufficiency reduces the extent of pulmonary congestion. After dilatation, hypertrophy occurs to normalize wall stress.[8]

The resistance to ventricular emptying (left ventricular afterload) is reduced because of the systolic regurgitation. This systolic unloading of the ventricle is a reason why patients with chronic mitral insufficiency remain well for many years.[9] The reduced load on the left ventricle allows a greater proportion of the contractile energy of the myocardium to be expended in shortening rather than in tension development. As a consequence of reduced afterload, patients with severe mitral insufficiency may show a small increase of ejection phase indices of myocardial contractility, such as ejection fraction and velocity of circumferential fiber shortening.[10]

As mitral insufficiency persists, the above-mentioned compensatory mechanisms (namely, increased preload, increased compliance, increased wall thickness, and decreased afterload) will not be sufficient because of the impaired myocardial contractility that is characteristic of chronic overload. Symptoms of low cardiac output and of lung congestion develop. Changes of impaired myocardial contractility may be found before symptoms appear by end-diastolic stress volume indices,[11] which are relatively independent of loading conditions.

Symptoms

Since symptoms in chronic mitral insufficiency do not develop until the left ventricle fails, the time interval between the attack of rheumatic fever and the development of symptoms tends to be longer than in mitral stenosis, often exceeding two decades. Also, in contrast to mitral stenosis, symptoms of low cardiac output are more prominent and appear before symptoms of lung congestion. The gradual onset of dyspnea can progress to paroxysmal nocturnal dyspnea. However, the incidence of acute pulmonary edema is lower than in mitral stenosis because sudden elevations in left atrial pressure are less frequent.[12] Similarly, while hemoptysis and systemic embolization do occur in mitral insufficiency, they are less common than in mitral stenosis. The development of atrial fibrillation affects the course of the disease adversely, but not as dramatically as in mitral stenosis because left atrial pressure is not as severely elevated by atrial fibrillation in mitral regurgitation as in mitral stenosis.[12] Atrial fibrillation is also more common in mitral stenosis.

General Examination

The heart rate and blood pressure are usually normal. The peripheral arterial pulse is small in volume but often exhibits a brisk upstroke. Atrial fibrillation may develop in the later stages of the disease.

Precordial Examination

The cardiac impulse is diffuse, forceful, and displaced downward and laterally. A prominent left ventricular filling wave is

frequently palpable in early diastole. An aneurysmally dilated left atrium may produce visible and palpable pulsations to the right of the sternum.

Auscultation

The first heart sound is usually diminished unless the pathological process involves predominantly the posterior leaflet and spares the anterior leaflet.

Wide splitting of the second heart sound is common because of an earlier aortic component of the second sound. This splitting is possibly related to shortened left ventricular ejection time resulting from the diminished afterload.

A loud apical third sound is usually audible because of increased transmitral volume flow during the rapid filling phase.

The characteristic murmur of mitral insufficiency is a high-pitched holosystolic murmur beginning with the soft first sound and continuing beyond (and sometimes obscuring) the second sound. The murmur is loudest at the apex with radiation to the axilla and left infrascapular area. Radiation toward the sternum or aortic area may occur with posterior mitral leaflet regurgitation. There is little correlation between the intensity of the murmur and severity of the lesion. Mitral insufficiency murmurs diminish with maneuvers that decrease afterload, such as standing and amyl nitrite inhalation, and increase with maneuvers that increase afterload, such as squatting and phenylephrine infusion.

Electrocardiography

In chronic mitral insufficiency, the electrocardiogram exhibits evidence of left ventricular and left atrial enlargement. In an advanced case, atrial fibrillation may supervene. Approximately 15% of patients with chronic mitral insufficiency exhibit electrocardiographic evidence of right ventricular hypertrophy, and 5% show combined ventricular hypertrophy.[13]

Radiography

Early in the course of the disease, the cardiac shadow may be normal. Later, left atrial and left ventricular enlargements become evident. The left atrium is generally more enlarged in mitral incompetence than in mitral stenosis (Fig. 87–3). Pulmonary hilar congestion with redistribution of flow to upper lobes, interstitial edema, and Kerley B lines appear with the development of left ventricular failure. Fluoroscopy may show systolic expansion of the left atrium. Calcification of the mitral valve is less common than in mitral stenosis and, when present, usually represents a mixed lesion.

Echocardiography

Echocardiography is useful not only in identifying the etiology of mitral insufficiency but also in determining its degree, in evaluating left ventricular function, and in determining the prognosis after mitral valve replacement.

M-Mode Echocardiography

Since mitral stenosis and insufficiency often coexist in rheumatic heart disease, an M-mode echocardiogram of the mitral valve often shows also the typical signs of mitral stenosis.[14] A number of M-mode echocardiographic signs, such as excessive mitral valve motion and a steep E-F slope,[15] suggest chronic mitral regurgitation. However, these signs do not constitute a specific finding for mitral insufficiency, since they can be observed in a variety of conditions that cause an increase in mitral valve flow. Furthermore, if there is fibrosis from rheumatic mitral disease, mitral valve motion is diminished.

Exaggerated septal motion is common in patients with chronic mitral insufficiency, but this sign may also be found in patients with other causes of volume overload of the left ventricle, particularly aortic regurgitation.

Increase in left ventricular diastolic dimension and significant decrease in left ventricular diameter during the pre-ejection phase can be detected. The latter sign is caused by the loss of the isovolumic contraction period because of the incompetent valve.[16]

A dilated left atrium and systolic expansion of the posterior left atrial wall have been proposed as useful signs of mitral insufficiency[17] (Fig. 87–4). However, these posterior left atrial wall pulsations are infrequently seen with mitral regurgitation. Furthermore, a similar finding has been noted in normal subjects and in patients with ventricular septal defect.[18] No clear correlation was found between the severity of the disease and left atrial diameter.[19]

Although none of these M-mode echocardiographic findings is specific for the diagnosis of chronic mitral insufficiency, a combination of these findings in conjunction with the appropriate clinical picture is helpful. M-mode echocardiography may also be of value in terms of prognosis in patients with mitral insufficiency. Persistence of symptoms and poor long-term prognosis have been observed after mitral valve replacement if the left ventricular end-

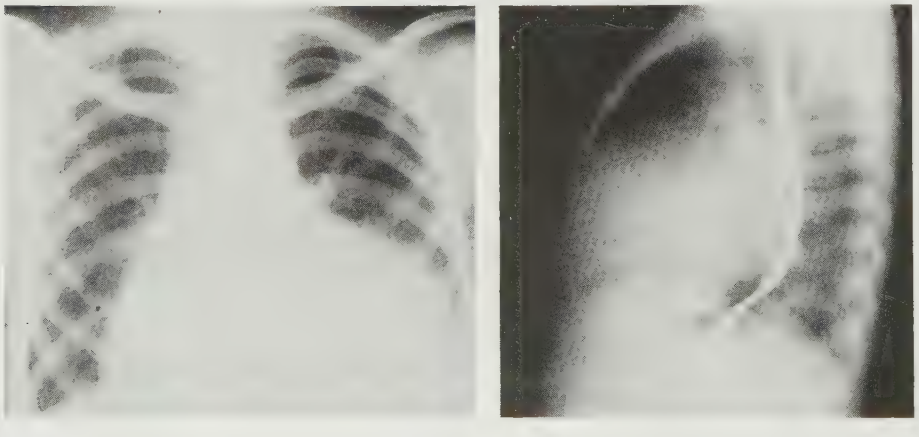

Fig. 87–3. Posteroanterior and lateral chest radiographs from a patient with advanced rheumatic mitral and aortic valve diseases showing gross cardiac enlargement.

systolic dimension exceeds 2.6 cm/m², the end-diastolic dimension exceeds 4 cm/m², or the fractional shortening was less than 31%.[20,21] Symptomatic improvement after mitral valve replacement has been associated with a decrease in left atrial size postoperatively.[19] Persistent left atrial dilatation with atrial fibrillation after mitral valve replacement for mitral regurgitation has also been found to indicate a poor prognosis.

Two-Dimensional Echocardiography

Two-dimensional echocardiographic findings in rheumatic mitral regurgitation include thickened mitral valve leaflets, incomplete closure of the mitral valve, relatively immobile posterior mitral leaflet, dilated left atrium with systolic expansion, and dilated left ventricle with hyperdynamic septal and posterior wall motion.[14]

Doppler Echocardiography

Doppler echocardiography has an important role in both diagnosis and quantification of mitral insufficiency with a very high degree of specificity and sensitivity.[19,23,24]

The degree of mitral insufficiency can be assessed by the depth of extension of the regurgitation into the left atrium, by the intensity of the Doppler signal from the regurgitation, and by increases in forward flow velocity.[19,23–25]

Using color Doppler flow mapping, only a weak relationship has been observed between jet size and regurgitant volume or fraction. No correlation is found between jet size and any measurement of cardiac pressure or flow. However, a general correlation was observed between jet size and end-diastolic volume index, a finding suggesting that color Doppler flow mapping may reflect the volume overload imposed by mitral regurgitation.[26]

Radioisotope Angiography

Radionuclide techniques can measure the end-diastolic and end-systolic volumes, estimate the regurgitant fraction, and assess the left ventricular function by estimating the ejection fraction.[27,28]

Cardiac Catheterization and Angiography

Cardiac catheterization usually demonstrates elevated left atrial pressure. The v wave is particularly elevated. There is a prompt Y descent unless mitral stenosis is associated. The effective forward cardiac output is usually depressed. The total left ventricular output (forward and regurgitant) is usually elevated unless left ventricular dysfunction supervenes. Although a left atrioventricular pressure gradient persisting throughout diastole signifies the presence of associated mitral stenosis, an early diastolic gradient may occur in patients with severe regurgitation as a result of torrential blood flow across a normal-sized mitral orifice. The pulmonary artery and right ventricular pressures may be elevated in severe long-standing cases associated with increased pulmonary vascular resistance.

The diagnosis of mitral regurgitation is usually established by means of left ventriculography. Mitral regurgitation is indicated by the appearance of contrast material in the left atrium following left ventricular injection. Mitral regurgitation due to rheumatic involvement is characterized by a central regurgitant jet and by thickened leaflets that exhibit reduced motion. This is in contradistinction to other causes of mitral regurgitation (e.g., dilated annulus, ruptured chordae) in which the regurgitant jet is eccentric and the valve is thin and hypermobile. The regurgitant volume can be determined from the difference between the total left ventricular stroke volume (estimated angiocardiographically) and the simultaneous measurement of the effective forward stroke volume by Fick's method.

One of the important objectives of cardiac catheterization in

patients with mitral insufficiency is the assessment of left ventricular function. The end-systolic indices, being unaffected by the loading conditions, are more reliable than ejection indices in assessing ventricular function in chronic mitral insufficiency.[11]

RHEUMATIC MITRAL STENOSIS

Stenosis of the mitral valve is usually secondary to rheumatic carditis. However, a number of other less common etiologies exist, such as congenital mitral stenosis, atrial myxoma, infective endocarditis with bulky vegetations, and mucopolysaccharidoses of the Hunter-Hurler phenotype.[29] The combination of mitral stenosis and secundum atrial septal defect is frequently referred to as Lutembacher's syndrome. In most cases, the mitral stenosis is rheumatic, and the association with atrial septal defect is fortuitous,[30] although the original report of mitral stenosis was felt to be the result of associated congenital cardiac malformations.

In patients with mitral stenosis, a history of rheumatic fever is obtained in only about two thirds of cases. In the remainder, the acute attack presumably escapes clinical recognition. It is still not clear whether the pathological changes seen in mitral stenosis are the result of subclinical rheumatic carditis or trauma produced by turbulent flow across a valve that has been deformed by the initial rheumatic process.

Pathology

Rheumatic fever causes mitral stenosis through fusion of the commissures, cusps, and/or chordae tendineae of the mitral valve apparatus. Commissural thickening and fusion make up the predominant lesion.

The stenosed mitral valve is typically funnel shaped, and the orifice is frequently shaped like a "fish mouth" or "buttonhole" (Fig. 87–5). Fibrosis is usually more marked at the periphery of the anterior cusp. The central part of the anterior cusp is less rigid and pliable. The opening snap and accentuated first heart sound characteristic of mitral stenosis are due to the up and down motions, respectively, of the central part of the anterior leaflet with ventricular diastole and systole. Calcium may be deposited in the valve leaflets, sometimes extending to involve the valve ring, and may become quite thick.[31] Occasionally, the thickened cusps may be so adherent to each other and pulled downward by the shortened chordae that they cannot open or close, thus reducing or abolishing the first sound and leading to combined mitral stenosis and insufficiency.

The left atrium is characteristically enlarged. Mural thrombosis may be present, most commonly involving the free wall just above the posterior cusp (MacCallum's patch). In long-standing cases, plaques of calcium may develop on the left atrial endocardial surface. Left atrial dilation may lead to elevation of the left main stem bronchus. The left ventricle is usually normal or reduced in size in pure mitral stenosis. Changes of pulmonary venous congestion, pulmonary hypertension, and hemosiderosis may develop in the lungs. It is usual to find dilation and hypertrophy of the right ventricle and functional tricuspid regurgitation.

Pathophysiology

Obstruction to flow across the narrowed mitral valve produces a diastolic gradient between the left atrium and the left ventricle. The left atrium–left ventricle diastolic gradient is related to the orifice size and the diastolic flow. The latter is determined by the cardiac output and by the duration of diastole. Serious circulatory disturbances with consequent clinical symptoms develop in adults when the area of the mitral opening is less than 1 cm^2. These data are not available for children. As narrowing proceeds, left atrial pressure increases, and blood stagnates in the pulmonary veins and capillaries, causing lung congestion (Fig. 87–6). Pulmonary arteriolar vasoconstriction occurs to protect the lungs against congestion. This occurs at the expense of developing pulmonary hypertension, which leads to right ventricular hypertrophy and eventually to right heart failure.

In the vast majority of patients with isolated mitral stenosis, the left ventricular end-diastolic volume is within the normal range. In a minority, it is below normal; and rarely, left ventricular volume is increased. Left ventricular contractility, as estimated

The valve on the left is the tricuspid valve and is showing gross tricuspid insufficiency. The latter occurs in later stages of mitral stenosis because of the long-standing severe secondary pulmonary hypertension. (Courtesy of Dr. Soheir Mahfouz, Pathology Dept., Cairo University.)

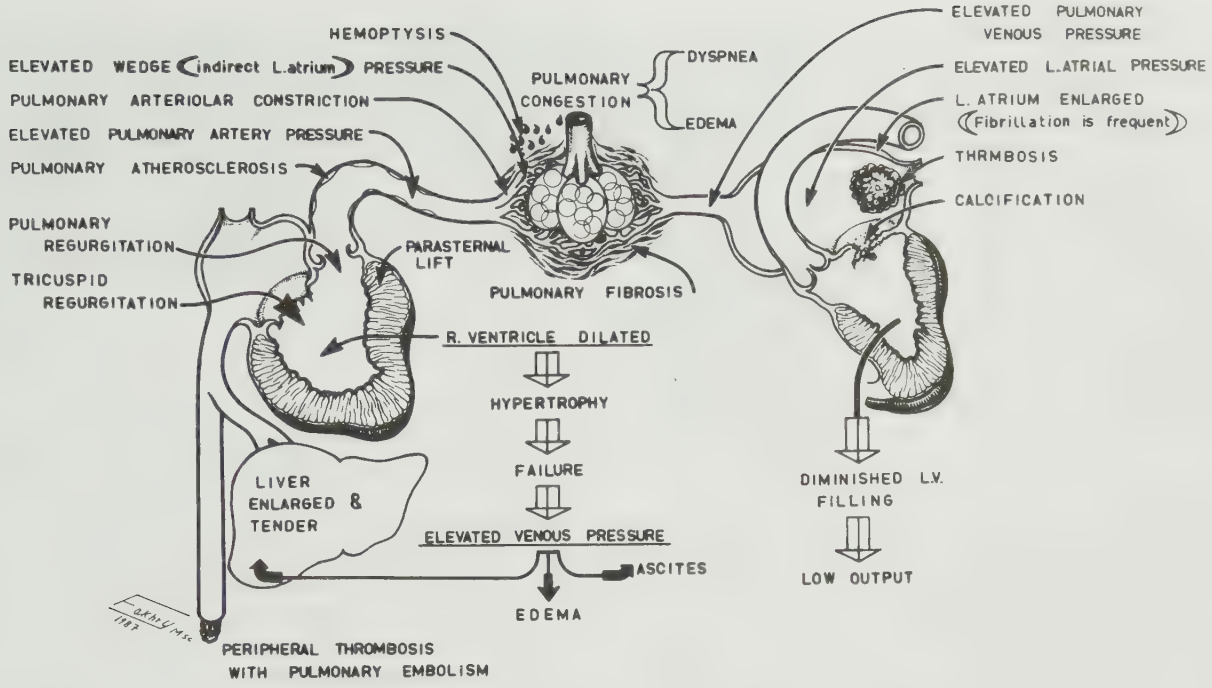

Fig. 87–6. A diagram depicting the hemodynamic alterations and complications that occur secondary to mitral stenosis.

by ejection phase indices, is within normal in the majority of patients. In approximately 30% of patients, left ventricular function is below normal, most likely owing to chronic reduction in preload and perhaps to the extension of the scarring process from the mitral valve into the adjacent posterobasal myocardium[32] or to low-level rheumatic carditis.

Fibrosis and disorganization of left atrial muscle bundles frequently occur in mitral stenosis as a result of the rheumatic process or as a consequence of left atrial dilatation caused by elevated left atrial pressure. Such changes lead to inhomogeneous conduction velocities and refractory periods and associated arrhythmias.

Symptoms

The symptoms of mitral stenosis may appear insidiously within three or four years after the attack of acute rheumatic fever. However, evidence of rheumatic mitral stenosis may be delayed up to 50 years. Some patients never develop symptoms. Sometimes the onset is abrupt, caused by the occurrence of a complication such as acute pulmonary edema, systemic embolism, or atrial fibrillation.

The symptoms depend upon the stage of the disease. Symptoms are absent in mild mitral stenosis. When pulmonary venous hypertension occurs, there is dyspnea, orthopnea, nocturnal dyspnea, recurrent chest infections, and hemoptysis. When pulmonary hypertension develops, symptoms caused by lung congestion diminish, and low cardiac output symptoms supervene. Symptoms caused by systemic congestion appear if the right ventricle fails.

General Examination

General examination reveals no abnormalities in mild cases. With the development of pulmonary hypertension, the face may show "malar flush,"[33] which is characterized by a cyanotic flush over the cheeks and dusky cyanosis of the lips partially caused by peripheral oxygen desaturation resulting from the low cardiac output. The jugular venous pulse shows a prominent a wave. The pulse is usually normal unless atrial fibrillation supervenes.

Precordial Examination

The apical impulse is felt at its site as a hurried slapping impulse. A characteristic diastolic or presystolic thrill ending in a palpable accentuated first sound is felt over the apex. When pulmonary hypertension develops, signs of enlargement of the pulmonary artery and hypertrophy of the right ventricle are detected. If right ventricular hypertrophy starts at a young age, a precordial bulge develops.

Auscultation

The first sound is loud, short, and snappy. The accentuation of the first sound is due to the open position of the cusps in the left ventricle at the end of diastole. This occurs because of the high pressure in and the continued emptying of the left atrium. The accentuation is also partly a result of the fibrotic changes in the cusps. The first sound loses its snappy character when calcification of the cusps supervenes. An opening snap, which is a sharp, clicky sound separated from the second sound by the isovolumic relaxation phase, may be present. The opening snap is caused by the sudden opening of the rigid mitral valve by the high left atrial pressure. The interval between the second sound and the opening snap decreases with increase in the degree of tightness, since increase of the left atrial pressure leads to early opening of the mitral valve.[34] The diastolic murmur of mitral stenosis is a low-pitched rumbling murmur that is best heard at the apex with the bell of the stethoscope. Although the intensity of the diastolic murmur is not closely related to the severity of the stenosis, the duration of the murmur is a guide to the degree of mitral obstruction. The murmur usually starts immediately after the mitral open-

ing snap. In mild cases, the murmur is brief. In severe stenosis, the murmur is holodiastolic with presystolic accentuation. Auscultation of the diastolic murmur of mitral stenosis is often facilitated by placing the patient in the left lateral position and listening during expiration after a few sit-ups. When pulmonary hypertension occurs, typical auscultatory phenomena appear, such as accentuated pulmonary second sound, narrow splitting of the second sound, and pulmonary ejection systolic click. There may be an ejection systolic murmur heard over the pulmonary artery from dilatation of the pulmonary artery. When dilatation of the pulmonary ring occurs, an early diastolic murmur of pulmonary insufficiency, Graham Steell's murmur, is heard. With severe pulmonary hypertension and decrease of blood flow across the mitral valve, the diastolic murmur of mitral stenosis again becomes shorter.

Electrocardiography

The electrocardiogram is normal in mild mitral stenosis. In patients with moderate or severe obstruction, the principal feature is left atrial enlargement (P-mitrale), which is demonstrated in 90% of patients with significant lesions.

The electrocardiographic signs of left atrial enlargement correlate more closely with left atrial volume than with left atrial pressure.[35] When atrial fibrillation supervenes, the fibrillatory waves are usually coarse (greater than 0.1 mV in amplitude in lead V_1), also suggesting the presence of atrial enlargement.[36] Electrocardiographic evidence of right ventricular hypertrophy depends on the level of right ventricular systolic pressure (Fig. 87–7).

Radiography

Findings depend on the severity of the disease. The cardiac silhouette may be normal in mild cases. In patients with hemodynamically significant mitral stenosis, left atrial enlargement is almost invariably evident on the lateral and right anterior oblique views (Fig. 87–8). The size of the left atrium does not correlate with the severity of the obstruction. Enlargement of the pulmonary artery, right ventricle, and right atrium is usual in mitral stenosis, depending on the severity of the disease (Fig. 87–9). Occasional calcification of the mitral valve is evident.

With chronic pulmonary venous hypertension, there is not only prominence of the pulmonary veins but also a redistribution of the flow toward the apices of the lungs. Interstitial edema is an indication of severe obstruction with pulmonary capillary pressure exceeding the oncotic pressure of the plasma protein (20 to 25 mm Hg). Kerley B lines are dense, short, horizontal lines most commonly seen at the costophrenic angles[37] that are thought to represent dilated pulmonary lymphatics.

Echocardiography

M-Mode Echocardiography

The M-mode echocardiographic criteria for the diagnosis of mitral stenosis include a reduced EF slope of the anterior mitral leaflet (Fig. 87–10). This finding is not highly specific. A reduced EF slope can be observed in patients with reduced left ventricular compliance. The EF slope is a function of the rate of filling of the left ventricle.[38] A poor correlation ($r = 0.41$) was detected between the degree of reduction of EF slope and the hemodynamically determined mitral valve area.

The posterior mitral leaflet moves parallel to the anterior mitral leaflet, so both leaflets move anteriorly in diastole. This results from commissural fusion and is considered the main diagnostic hallmark of mitral stenosis.[38] However, the posterior mitral leaflet can move posteriorly in patients with mild mitral stenosis.

Thickened mitral valve leaflets occur as a result of fibrosis and/or calcification. There can be decreased mitral valve excursion and separation of the two leaflets.

Two-Dimensional Echocardiography

The diagnostic feature of mitral stenosis in two-dimensional echocardiography (Fig. 87–11) is doming of the anterior leaflet in diastole; that is, the body of the leaflet separates more widely than the edges. The posterior leaflet is frequently stiff and appears severely restricted in diastolic movement. While M-mode echocardiography is of limited value in the quantification of the degree of stenosis in a given patient, an approximation of the severity

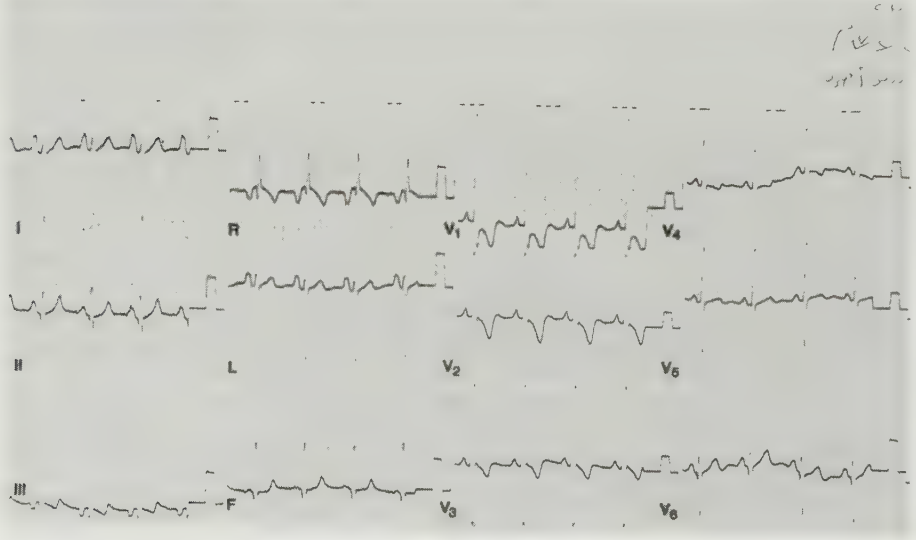

Fig. 87–7. An electrocardiogram from an advanced case of mitral stenosis with pulmonary hypertension, showing biatrial enlargement, right ventricular hypertrophy, and strain.

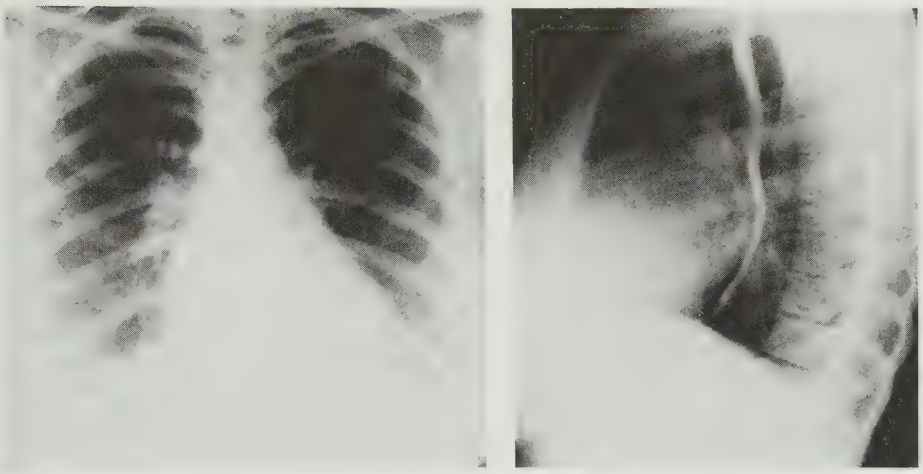

Fig. 87–8. Posteroanterior and lateral views from a patient with mitral stenosis showing mitralization of the heart, enlarged left atrium, and lung congestion.

can be achieved by two-dimensional echocardiography. Mitral valve area, in a short-axis view in diastole, can be measured by planimetry. The maximum diastolic separation of the edges of both leaflets in the long-axis view indicates the approximate severity of mitral stenosis and should be used in conjunction with a short-axis view for quantification. A favorable comparison of two-dimensional echocardiographically derived mitral valve area with mitral valve area measured directly at surgery has been reported by several authors.[19,39,40]

Orifice measurement at the *tip* of the funnel created by the opened mitral valve is required for accuracy. Scanning the mitral valve toward the base of the cusps (the area in which arching of the anterior leaflet occurs) results in underestimation of the severity of stenosis by echocardiography[19] and an orifice measurement that is larger than is really present.

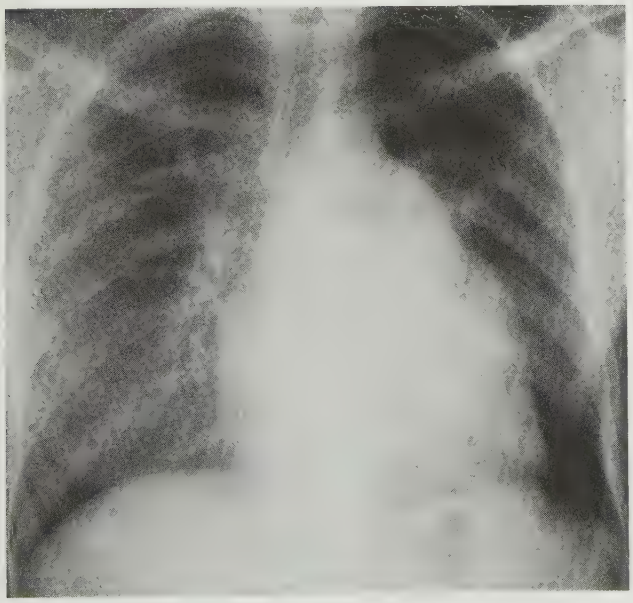

Fig. 87–9. Posteroanterior view from a patient with advanced mitral stenosis and pulmonary hypertension showing aneurysmal left atrium bulging on the left and right borders of the heart and enlarged pulmonary artery.

Doppler Echocardiography

Doppler echocardiography provides information about the flow of blood across the mitral valve and is useful in conjunction with two-dimensional echocardiography in evaluating mitral stenosis.

The Doppler flow profile of a normal mitral valve looks similar in configuration to the M-mode tracing with an early diastolic peak, a rapid fall, and a late diastolic peak. The velocity of the Doppler signal across the mitral valve reflects the pressure gradient between the left atrium and the left ventricle in diastole. The normal mitral valve peak velocity does not exceed 1.2 mm/s. In mitral stenosis, the diastolic velocity is higher and exceeds 1.5 mm/s. Also, the slower decline in the diastolic pressure gradient across the mitral valve results in a slower velocity drop during diastole. As the stenosis increases, the diastolic gradient increases for a longer time, and the negative descent of the diastolic Doppler velocity becomes slower.

There are two methods to estimate the severity of mitral stenosis from the Doppler signal. Instantaneous pressure drop (Δ P) between two chambers can be calculated from the Doppler velocity (V) by using a modified Bernoulli equation ($\Delta P = r \times V^2$). The mitral valve Doppler tracing can be used to determine both mean and instantaneous pressure gradients across the mitral valve. The correlation between simultaneous cardiac catheterization and pressure gradients calculated from Doppler echocardiography is excellent.[13–19,41–45] The second method for quantification of the severity of mitral stenosis uses diastolic half-time ($t\frac{1}{2}$). As the stenosis becomes more severe, the decline in pressure gradient during the diastole of the cardiac cycle between left atrium and left ventricle is slower. The rate of decline can be measured by the "$t\frac{1}{2}$," which is the time it takes for the velocity to decrease to 50%. This is an accurate measurement of the severity of mitral stenosis. The diastolic pressure half-time is inversely proportional to the mitral valve area and is independent of heart rate, coexistent mitral insufficiency, or atrial fibrillation. Normally, $t\frac{1}{2}$ is 20 to 60 ms. In mitral stenosis, it reaches 90 to >300 ms. Hatle and associates[46] found that by dividing 220 by the $t\frac{1}{2}$, a value for the mitral valve area could be obtained directly. Measurement of the diastolic $t\frac{1}{2}$ by Doppler echocardiography is highly accurate in comparison with cardiac catheterization measurements.[17–19]

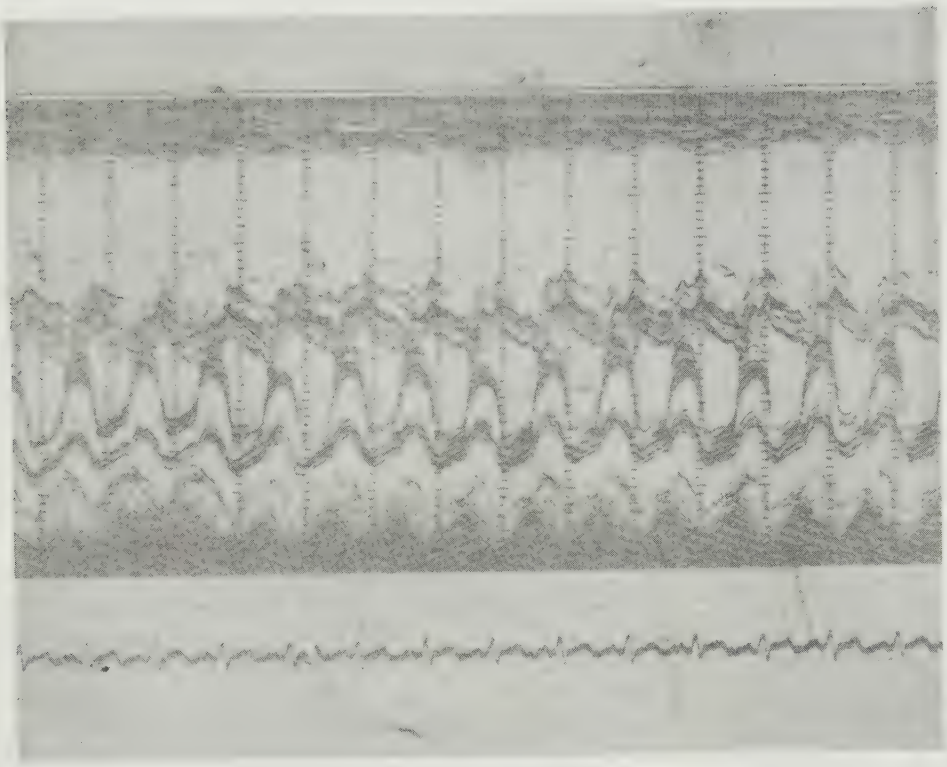

Fig. 87–10. M-mode echocardiogram from a patient with mitral stenosis showing slow EF slope, thickened mitral leaflets, and concordant movement of the anterior and posterior leaflets. The right ventricle is enlarged, indicating the presence of pulmonary hypertension.

Cardiac Catheterization and Angiography

Cardiac catheterization and angiography are not usually necessary in isolated mitral stenosis but may still be performed in atypical cases. In patients with mild severity by noninvasive assessment but significant symptoms, cardiac catheterization might be needed. The characteristic findings at catheterization include elevated left atrial and pulmonary capillary wedge pressures. In patients with sinus rhythm, the left atrial pressure pulse often exhibits a prominent atrial contraction a wave and a gradual pressure decline after mitral valve opening Y descent; the mean left atrial pressure is elevated (Fig. 87–12). In patients with mild-to-moderate stenosis without elevation of pulmonary vascular resistance, pulmonary artery pressure may be normal at rest and rise only during exercise. However, in patients with severe stenosis

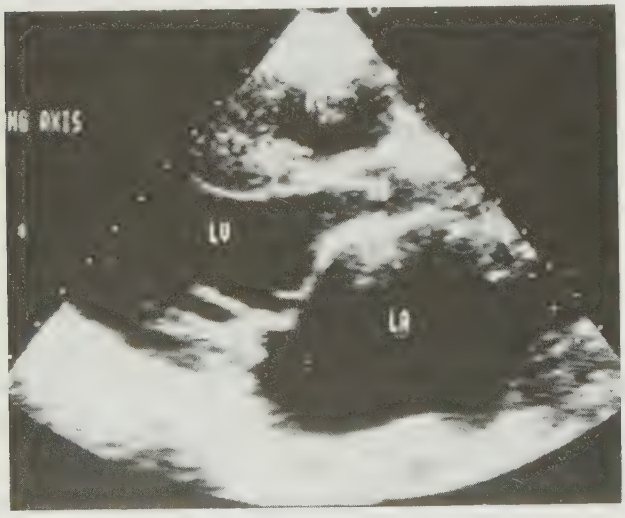

Fig. 87–11. Two-dimensional echocardiogram from a patient with mitral stenosis showing incomplete opening of the mitral valve. The anterior leaflet is doming, while the posterior leaflet is restricted. The left atrium (LA) is markedly enlarged. LV = left ventricle; RV = right ventricle; AO = aorta.

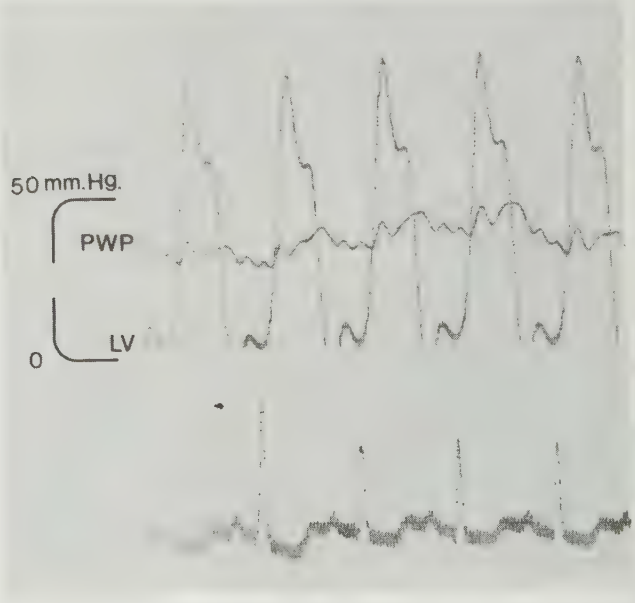

Fig. 87–12. Simultaneous left ventricular (LV) and pulmonary capillary wedge (PWP) pressures from a patient with mitral stenosis showing significant diastolic gradient across the mitral valve.

and those in whom the pulmonary vascular resistance is significantly increased, pulmonary arterial pressure is elevated at rest.

If mitral stenosis is of indeterminate severity, it is extremely important to exercise the patient because a small difference between the left ventricular end-diastolic pressure and the left atrial pressure can increase markedly during exercise, particularly when the resting cardiac output is low. Consequently, what seems to be only mild stenosis at rest as judged by the resting gradient clearly becomes severe stenosis when exercise is performed.

Diagnosis

The diagnosis of mitral stenosis is usually straightforward on the basis of history, physical signs, and chest roentgenogram and can be rapidly confirmed by echocardiography. An attempt should be made to quantify the severity of the mitral stenosis as well as to diagnose its presence. Quite reliably, this can be achieved from the history, the length of the diastolic murmur, the presence and severity of pulmonary hypertension, and right ventricular hypertrophy. Measurement of the mitral diastolic pressure gradient or the valve area at cardiac catheterization allows the obstruction to blood flow to be quantitated, and it is also possible to measure the left ventricular filling pattern either by echocardiography or by Doppler methods that give similar information. With limitations, valve area can be assessed directly by planimetry using two-dimensional echocardiography and indirectly by Doppler methods using pressure half-time measurements.

There are several conditions that may mimic mitral stenosis. These include left atrial myxoma, cor triatriatum, pulmonary veno-occlusive disease, and Austin Flint murmur from aortic regurgitation.

Left Atrial Myxoma

Left atrial myxoma may mimic all the physical signs of mitral stenosis including mid-diastolic and presystolic murmurs, loud first sound, and an opening snap known as a "tumor plop." It may lead to dyspnea and to systemic embolization. Variable murmurs are often described; however, constant murmurs or a total absence of auscultatory abnormalities is equally characteristic. Echocardiography is diagnostic and shows a characteristic mass of echoes behind the mitral valve during diastole. Atrial myxoma is less common in series of pediatric cardiac tumor cases than in adult cardiac tumor series, as is discussed in Chapter 96.

Cor Triatriatum

The congenital anomaly cor triatriatum may lead to obstruction of blood flow at the atrial level and may mimic mitral stenosis, particularly in childhood. Elevations of both pulmonary venous pressure and pulmonary vascular resistance result in severe pulmonary artery hypertension. The diagnosis should be suspected at cardiac catheterization if the pulmonary artery wedge pressure is higher than a simultaneous left atrial pressure. The diagnosis is established by visualizing the obstructing lesion echocardiographically or angiographically. A more complete discussion may be found in Chapter 77.

Pulmonary Veno-Occlusive Disease

Pulmonary veno-occlusive disease is an extremely rare condition of unknown etiology that has been reported in infants, children, and occasionally adults. In this disease, one finds intimal fibrosis affecting pulmonary veins of all sizes. Individual veins may show concentric or eccentric narrowing or complete occlusion. The appearances of these veins suggest recanalization following organization of thrombus. Pulmonary venous hypertension results in pulmonary arterial hypertension and right ventricular hypertrophy. This condition may stimulate silent mitral stenosis, but there is no left atrial enlargement. Because the condition may be patchy, pulmonary artery wedge pressure may be high or low according to whether the catheter is wedged in an affected or unaffected segment of the lung. Lung biopsy may be required in establishing this diagnosis.

Austin Flint Murmur from Aortic Regurgitation

In the presence of severe aortic regurgitation, a mid-diastolic murmur may be audible at the cardiac apex in the absence of organic mitral valve disease. This murmur can be presystolic rather than mid-diastolic on occasion. The murmur is the result of fluttering of the anterior leaflet of the mitral valve caused by the regurgitant stream. On clinical grounds, this murmur may sometimes be differentiated from coexistent mitral stenosis by the fact that, in the Austin Flint murmur, the first sound is never palpable, and an opening snap is never present. Echocardiography and Doppler examination are usually required for certainty.

LUTEMBACHER'S SYNDROME

Patients with rheumatic mitral stenosis may have associated atrial septal defect, a combination known as Lutembacher's syndrome.[30] The combination is still seen in areas where rheumatic heart disease is prevalent.

The atrial septal defect exerts a protective effect on the lungs in mitral stenosis by decompressing the left atrium. However, the high left atrial pressure secondary to mitral stenosis exaggerates the left-to-right shunt across the atrial septal defect with its consequences on the lungs.

Patients are virtually always symptomatic from increased lung flow, liver congestion, and low cardiac output. However, "cardiac asthma" and orthopnea do not occur. The findings on examination suggest both lesions. Errors may occur in diagnosis. A patient with both lesions may be thought to have mitral stenosis or atrial septal defect. Constant splitting of the second sound with mitral stenosis indicates associated atrial septal defect. An electrocardiogram with an RSR′ pattern in the right chest leads (Fig. 87–13), or a chest roentgenogram with a markedly enlarged pulmonary artery and plethoric lungs (Fig. 87–14) in a patient with mitral stenosis, should suggest associated atrial septal defect. Echocardiography is very helpful (Fig. 87–15), since it can show both lesions. Cardiac catheterization reveals excessive pulmonary flow. The gradient across the stenotic mitral valve is usually small or absent with large atrial septal defect and diagnosis depends on angiography (Figs. 87–16, 87–17).

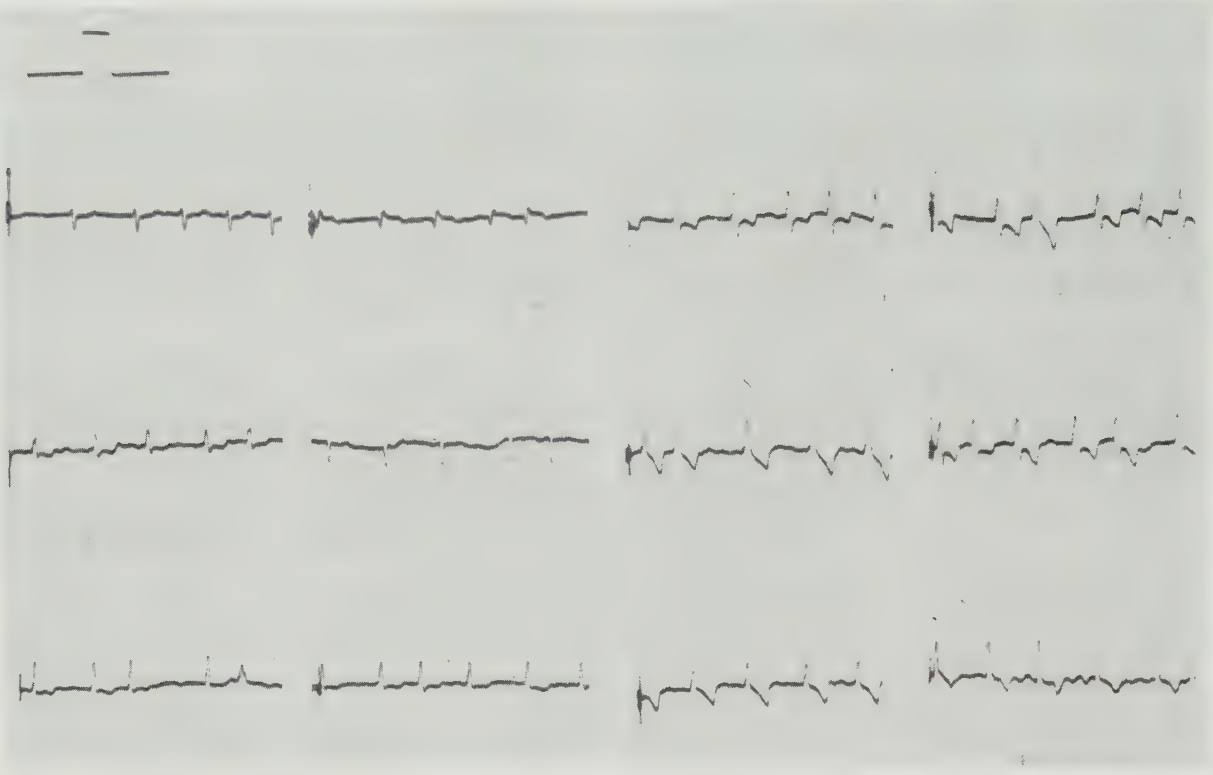

Fig. 87–13. The presence of rSR in V_1 in this patient with the clinical diagnosis of mitral stenosis suggested additional atrial septal defect. The patient also had atrial fibrillation.

AORTIC VALVE DISEASE

Aortic valvulitis, which may develop during rheumatic carditis, may cause aortic insufficiency and/or stenosis. Insufficiency, which results from damage of the aortic leaflets, occurs early in the course of the disease and may be exaggerated by time because of fibrosis, thickening, and contracture of the aortic leaflets (Fig. 87–18). Stenosis resulting from fusion of the commissures takes a long time to develop. As a result, aortic valve disease of rheumatic etiology in children and adolescents usually presents as isolated or dominant insufficiency with mild or no stenosis. Dominant stenosis with or without insufficiency at a young age is usually congenital. A rheumatic aortic valve has a characteristic appearance of a tricuspid valve with thickened cusps, rolled edges, and fused commissures.

Pathophysiology

The inability of the shortened aortic leaflets to coapt and close the aortic orifice completely during ventricular diastole causes diastolic regurgitation of blood from the aorta to the left ventricle (Fig. 87–19). Since the normal aortic diastolic pressure approximates 80 mm Hg and the normal left ventricular diastolic pressure is 0 to 12 mm Hg, any degree of aortic insufficiency may lead to significant regurgitation. A regurgitant area of approximately 20% of the aortic orifice area can double total left ventricular output and left ventricular work.[47] With severe aortic insufficiency, the

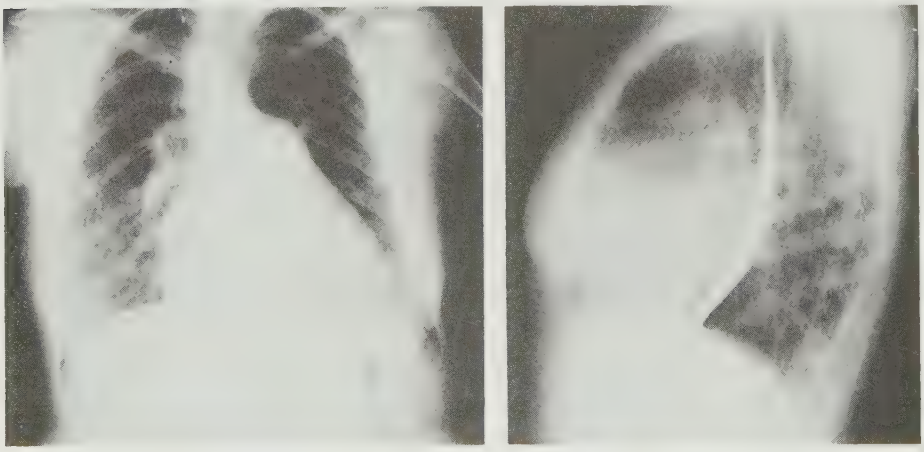

Fig. 87–14. Posteroanterior and lateral views from the patient of Fig. 87–13. The enlarged pulmonary artery and lung plethora also suggest associated atrial septal defect. The left atrium is slightly enlarged.

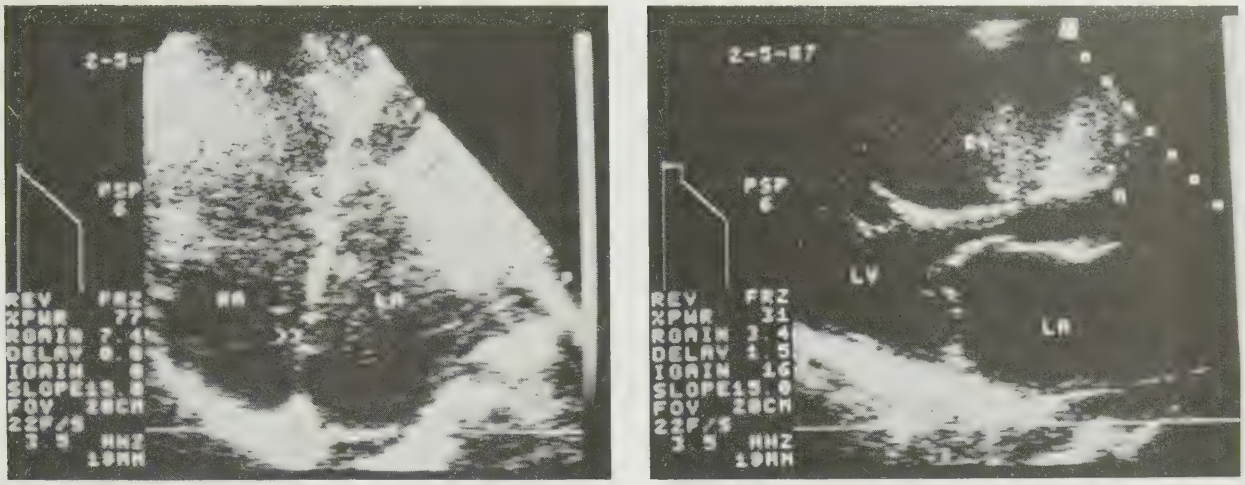

Fig. 87–15. Two-dimensional echocardiogram from the patient of Fig. 87–13. The right section is a longitudinal one showing mitral stenosis and the left is a subcostal view, confirming the presence of associated secundum atrial septal defect. RA = right atrium; RV = right ventricle; LA = left atrium; A = aorta.

diastolic leak into the left ventricle may be as high as 60% or more of the left ventricular stroke volume.[48]

With chronic aortic insufficiency, the left ventricle dilates and accommodates more blood for many years. The increase in left ventricular diastolic volume is not accompanied by an increase in end-diastolic pressure probably because of an increase in the left ventricular diastolic compliance. The increase in left ventricular end-diastolic volume encroaches on preload reserve and, according to Starling's law, increases stroke volume.[49,50] This compensatory mechanism is aided by reduced aortic impedance (and therefore afterload), which occurs because of reflex peripheral vasodilation. Another compensatory mechanism is eccentric left ventricular hypertrophy, which tends to normalize left ventricular wall stress as described by Laplace's law ($0 = Pa/2h$, where 0 is circumferential wall stress, P is intraventricular pressure, a is intraventricular radius, and h is wall thickness).[51,52]

Increase of left ventricular stroke volume with consequent elevation of the systolic blood pressure accompanied by decrease of the diastolic blood pressure (caused partly by regurgitation of a part of the stroke volume and partly by peripheral arteriolar vasodilation) leads to an increase in the pulse pressure. The classic peripheral arterial pulses of aortic insufficiency show a rapid rise to a high peak with a collapsing descending limb, an insignificant dicrotic notch, and a low diastolic pressure.[53]

Myocardial oxygen consumption increases with aortic insufficiency caused by increase of preload, left ventricular wall tension, and left ventricular mass. Since the major portion of coronary flow occurs during diastole, when arterial pressure is lower than normal, coronary perfusion is reduced,[54] and the increased oxygen demand and reduced coronary flow may lead to myocardial ischemia, especially with exercise.[55]

Exhaustion of the compensatory mechanisms (preload reserve, increased contractility, and diminished afterload) as well as myocardial ischemia may result in left ventricular failure. Because significant cardiac compensation is related to an increased ejection fraction, a "normal" ejection fraction suggests inadequate compensation in response to the regurgitation.[56] Decreased ejection fraction leads to increased end-systolic volume, which in turn

appears to be one of the most sensitive indices of myocardial dysfunction.[57] Ultimately, left ventricular end-diastolic pressure starts to rise. Levels as high as 60 mm Hg have been reported[58] and may equal the aortic diastolic pressure. Patients with severe aortic insufficiency have the largest left ventricular diastolic volumes of any form of heart disease.

With rise of left ventricular diastolic pressure, the magnitude of the aortic leak decreases with concomitant elevation of diastolic aortic pressure, reduction of the aortic insufficiency murmur, and reduction of peripheral signs. In some patients with this defect, the left ventricular diastolic pressure exceeds that in the left atrium in mid-diastole with consequent premature closure of the mitral valve.

In chronic aortic insufficiency, many of these compensatory and decompensatory changes occur before the onset of symptoms. The symptoms usually start only when the high left ventricular end-diastolic pressure is reflected on the left atrial and pulmonary capillary pressures. Progressive left ventricular dilatation may result in second mitral insufficiency, which leads to a rapid downhill course.

End-systolic indices (e.g., end-systolic pressure, volume, or stress volume relations) appear to be independent of the loading conditions and have proved to be superior to isovolumic (dp/dt, etc.) and ejection phase (fractional shortening, ejection fraction) indices in detecting early left ventricular dysfunction in individual cases.[11]

Associated aortic stenosis causes significant deleterious alterations in the pathophysiology. The increased stroke volume pro-

duced by aortic insufficiency causes a corresponding increase in the pressure gradient across the stenotic valve. At the same time, the decreased compliance of the left ventricle secondary to hypertrophy produced by the aortic stenosis leads to the inability of the left ventricle to accommodate the regurgitant blood of aortic insufficiency.

Symptoms

Early symptoms are unusual except with gross aortic insufficiency.

Patients may complain of cardiac awareness especially with exercise because of the large stroke volume and forceful left ventricular contractions. Those with severe aortic insufficiency may occasionally feel pain along the carotid arteries or even the abdominal aorta because of exaggerated pulsations of these arteries.[59] Excessive sweating and heat intolerance due to vasodilatation may be an early symptom. Chest pain may be a prominent symptom during exertion. Disturbing anginal pains may occur by night accompanied by tachycardia, sweating, and paroxysmal hypertension.

However, the main symptoms are caused by left ventricular decompensation, breathlessness being the most prominent symptom. Symptoms usually start on exertion, but nocturnal dyspnea or even an attack of acute pulmonary edema precipitated by severe exertion may be the presenting symptom.

Sudden death may occur in patients with uncontrollable angina, nocturnal angina, severe heart failure, and most commonly in patients with frequent ventricular arrhythmias.

Symptoms are exaggerated and occur earlier if aortic insufficiency is associated with aortic stenosis.

General Examination

The characteristic peripheral signs of aortic insufficiency are produced by the combined large pulse volume and peripheral vasodilation. The sharp rise of the pulse gives it a characteristic "water hammer" quality. The visible jerky arterial pulsations in the neck are known as Corrigan's sign. Nodding of the head with the strong heart beats is known as de Musset's sign. Duroziez's sign is elicited by compression of the femoral pulse and listening proximally for a diastolic murmur with the stethoscope. This implies retrograde flow in the femoral artery caused by aortic regurgitation of at least moderate severity. A systolic murmur elicited by this technique is heard normally and does not indicate the presence of aortic regurgitation. Capillary nailbed pulsations and exaggerated retinal artery pulsations can be elicited in severe aortic insufficiency.

The character of the pulse is modified in mixed aortic valve disease. With aortic stenosis, there is diminution of the pulse volume and a detectable notch halfway up the stroke. Pulsus bisferiens, which was previously considered to be associated with combined stenosis and insufficiency, is not an uncommon finding in pure aortic insufficiency.

The blood pressure is normal only in very mild aortic insufficiency. With increasing severity, the systolic pressure rises while the diastolic pressure falls. Indirect estimation of the diastolic pressure in severe aortic insufficiency is difficult because "pistol sounds" may be heard over the brachial artery without any pressure being applied by the cuff. This gives a false impression of a diastolic pressure of zero. In such patients, it is better to record the pressure at which sounds become muffled as well as the pressure at which they disappear. A reading of 160/40–0 is more appropriate than a reading of 160/0. The direct intra-arterial diastolic pressure is seldom below 40 mm Hg.[60] With a rise in left ventricular diastolic pressure, the magnitude of the aortic leak is reduced, as was explained. Hence some patients with gross aortic insufficiency may have a diastolic pressure of 60 mm Hg or more, especially when heart failure is complicated by peripheral vasoconstriction.

The venous pressure and waves are usually normal until late in the disease, unless a Bernheim a wave is produced. This is caused by the ventricular septum bulging to the right, thus retarding filling of the right ventricle.

Precordial Examination

The apical impulse in aortic valve disease is diffuse and hyperdynamic and may be displaced laterally and inferiorly. With severe aortic insufficiency, there is often a palpable apical diastolic thrust coincident with a left ventricular diastolic gallop.

A systolic thrill over the aortic area, which was thought to indicate the association of aortic stenosis, can be felt in severe isolated aortic insufficiency caused by increased left ventricular stroke output coupled with dilatation of the aortic root.

Auscultation

Heart sounds are normal in isolated aortic insufficiency. The aortic component of the second sound is weak if there is associated aortic stenosis.

The typical murmur of aortic insufficiency is an early diastolic high-pitched blowing decrescendo murmur over the base, which begins with the second sound. In rheumatic patients, the murmur is maximally heard parasternally over the second and third left intercostal spaces and may be propagated down to the apex. It is best heard with the diaphragm of the stethoscope while the patient is sitting and leaning forward in full expiration. The duration, rather than the quality or loudness of the aortic diastolic murmur, correlates with the severity of the aortic insufficiency. The aortic insufficiency murmur tends to decrease or disappear during pregnancy and to increase if the systemic resistance is elevated as by phenylephrine. When heart failure supervenes and the left ventricular diastolic pressure increases with consequent decrease of regurgitation, the intensity and duration of the aortic insufficiency murmur decrease or disappear completely.

An ejection systolic murmur at the base is heard in almost all cases of aortic insufficiency of more than mild degree because of increased blood flowing across the aortic valve in systole. The diagnosis of associated aortic stenosis cannot be made merely from the presence of this systolic murmur, since it may reach up to grade IV/VI with isolated significant aortic insufficiency.

A mid-diastolic or presystolic rumble over the mitral area, the Austin Flint murmur, is usually heard in patients with moderate or severe aortic insufficiency without associated organic mitral stenosis.[61] The Austin Flint murmur may be due to relative mitral stenosis secondary to improper opening of the anterior leaflet of the mitral valve either by the regurgitant bloodstream or by the high left ventricular diastolic pressure.[62] The Austin Flint murmur can also be caused by the addition of a diastolic or presystolic gallop to the aortic insufficiency murmur.[63] The Austin Flint murmur disappears lateral to the area of ventricular gallop. The Austin

Flint murmur usually occurs with left ventricular hypertrophy and with diastolic blood pressure of 60 mm Hg or less and is not accompanied by the opening snap or the accentuated first sound of organic mitral stenosis. Amyl nitrite decreases the Austin Flint murmur by decreasing systemic resistance but increases the mitral stenosis murmur because of tachycardia and increased cardiac output. The Austin Flint murmur is not accompanied by electrocardiogram, radiological, or echocardiogram manifestations of organic mitral stenosis. Echocardiography is now the most sensitive way of differentiation between an Austin Flint and an organic apical diastolic murmur.

Electrocardiography

The electrocardiogram is normal in mild and sometimes in severe aortic valve disease; 20% of operative candidates at Massachusetts General Hospital had no left ventricular hypertrophy by voltage criteria.[64] However, in most severe cases, left ventricular hypertrophy develops on the electrocardiogram. The changes at first consist mainly of increased QRS voltage in the left precordial leads. The T wave may be tall and upright at first; but later on, ST and T wave changes characteristic of strain develop[65,66] (Fig. 87–20). Left bundle branch block may appear in advanced cases. P wave changes of left atrial enlargement appear when left ventricular failure develops. Atrial fibrillation is rare in isolated aortic valve disease without mitral valve disease.

Radiography

In chronic aortic insufficiency, the chest radiograph provides more information than the electrocardiogram. As severity of aortic insufficiency increases, there is more dilatation and enlargement of the left ventricle. Typically, the left ventricle enlarges in an inferior and leftward direction and can be seen below the diaphragmatic level. The cardiothoracic ratio is related to the duration and severity of aortic insufficiency and consequently has value in predicting the outcome of surgical treatment.[62] Patients with a cardiothoracic ratio exceeding 0.64 have a postoperative death rate of 30% in contrast to 7% in patients with less cardiac enlargement.[67] The aortic root is usually dilated. Pulmonary venous congestion and generalized cardiac enlargement are seen when cardiac failure develops.

Echocardiography

The most common and characteristic M-mode echocardiographic finding in chronic aortic insufficiency is fine diastolic fluttering of the mitral valve, more frequently the anterior leaflet[68] (Fig. 87–21). Mitral valve fluttering, however, is not specific for aortic insufficiency[69] and may be absent in some patients, especially if mitral stenosis is also present. The sensitivity of this echocardiographic feature fell from 72% in isolated lesions to 40% when mitral stenosis was also present.[19]

Two-dimensional echocardiography is less useful than M-mode echocardiography in the recognition of chronic aortic insufficiency. However, it is more useful in identifying the etiology.

Reversed diastolic doming of the anterior mitral leaflet was detected by two-dimensional echocardiography in 19 of 22 patients[70] with moderately severe aortic insufficiency and in 13 of 25 patients[19] with severe aortic insufficiency and was not seen in normal subjects.

Apart from its diagnostic capabilities, echocardiography has an important role in the clinical assessment and in the evaluation of changes in left ventricular function in patients suffering from aortic insufficiency. In a serial echocardiographic study of patients with asymptomatic aortic insufficiency, Henry and associates[71] reported in 1980 that early left ventricular failure was more likely to occur when the end-systolic left ventricular dimension exceeded 55 mm or when the percent fractional shortening was less than 25%. Similar results were obtained in 1978 by Bonow and co-workers,[72] who showed that late deaths due to heart failure after aortic valve replacement occurred in patients with echocardiographically determined ejection fraction of 63% or less and left ventricular systolic dimension of 53 mm or more. Gaasch and associates[73] demonstrated in 1983 that patients with aortic insufficiency whose left ventricular end-diastolic diameter was more than 3.8 cm/m^2 were at risk of persistent postoperative left ventricular enlargement and reduced survival. On the basis of these studies, it was recommended that patients with asymptomatic aortic insufficiency and left ventricular end-systolic diameter of 50 mm be examined once

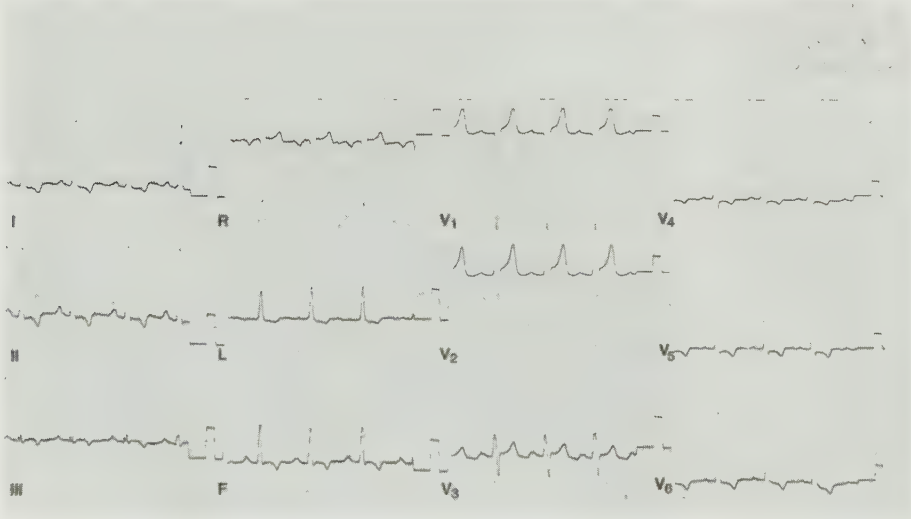

Fig. 87–20. An electrocardiogram showing severe left ventricular hypertrophy and strain from a patient with gross aortic insufficiency.

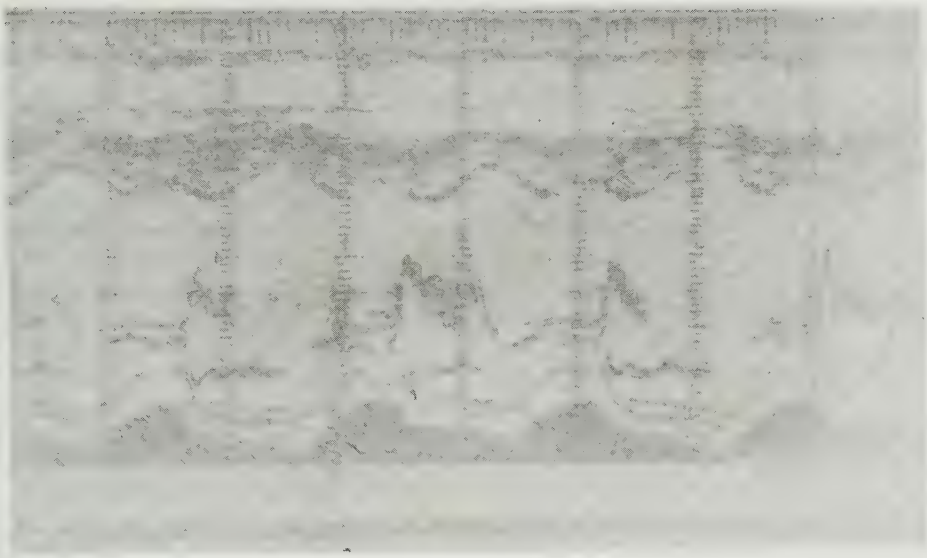

Fig. 87–21. M-mode echocardiogram showing fluttering of the anterior leaflet of the mitral valve caused by aortic insufficiency.

a year, patients with end-systolic diameter of 50 to 54 mm be examined once every four to six months, and aortic valve replacement be considered in asymptomatic patients with aortic insufficiency in which end-systolic diameter is greater than 55 mm. Later, studies by Fioretti and co-workers[74] in 1983 and Daniel and co-workers[75] in 1985 reported that both end-systolic diameter and end-diastolic diameter decreased postoperatively with long-term survival in patients who underwent aortic valve replacement for symptomatic aortic insufficiency who had preoperative end-systolic diameter greater than 55 mm. Patients who did not show marked decrease in end-diastolic diameter (by at least 11 mm) in the early postoperative period after aortic valve replacement seemed to have severe myocardial damage, and their prognosis was guarded.[76]

Other echocardiographic assessments of global function are based on estimates of left ventricular systolic wall stress (e.g., end-systolic wall stress or radius-to-thickness ratio).

Serial echocardiographic studies can detect early changes in left ventricular function. Deterioration is indicated if there is progressive increase in end-systolic and end-diastolic dimensions with gradual reduction of left ventricular shortening and ejection.

Doppler is the most sensitive noninvasive method of detecting aortic insufficiency. The diagnostic sensitivity of aortic insufficiency by Doppler ranged from 90%[19] to 97%.[77] The false-negative diagnoses of aortic insufficiency were encountered only in patients with angiographically mild insufficiency. This significantly high sensitivity has been reported in isolated lesions as well as in patients with associated mitral stenosis in whom echocardiography has proved less sensitive. Doppler has also proved satisfactorily specific in detecting aortic insufficiency. It showed a specificity of 92 to 100%.[19,78]

Accurate evaluation of the severity of aortic insufficiency by Doppler has not so far been satisfactorily achieved. However, several techniques for semiquantitative assessment of the severity of aortic insufficiency have been performed. Doppler echocardiographic measurement of the aortic regurgitant fraction has been performed by (1) comparing the forward and reverse flows in the aortic arch,[79] (2) comparing the systolic aortic and pulmonary volume flows,[80] (3) comparing the transmitral volumetric flow and the left ventricular total stroke volume, (4) measuring the extent of the regurgitant jet into the left ventricular outflow tract,[19,81] and (5) measuring the mitral pressure half-time.[82]

Color Doppler flow mapping of the regurgitant jet of aortic insufficiency offers a more precise approach to quantitating the severity of the leak.[83,84]

Cardiac Catheterization and Angiography

As has been discussed, left ventricular pressures are normal in aortic insufficiency until late in the disease. With left ventricular failure, there is elevation of left ventricular end-diastolic pressure with secondary elevation of left atrial and pulmonary capillary wedge pressures (Fig. 87–8). Associated aortic stenosis and/or mitral stenosis can be excluded by lack of gradients across the aortic and mitral valves.

Aortography (Fig. 87–9) is important to diagnose aortic insufficiency and grade its severity. There are four grades of quantification. One-plus represents a faint puff of regurgitation into the left ventricle. Two-plus indicates more regurgitation, which does not completely fill the ventricle. Three-plus indicates opacification of the entire left ventricle. Four-plus is applied if the opacification in the left ventricle equals that in the aorta.

Left ventriculography is an integral part of angiography for aortic insufficiency. It is helpful in determining the size of the left ventricle and the presence and degree of associated mitral regurgitation as well as in studying left ventricular function.

Course and Prognosis

Mild and moderate lesions are well tolerated for a long time.[85] Recurrence of rheumatic activity or the development of infective endocarditis initiates a rapid downhill progressive course. Severe aortic insufficiency may be tolerated for variable times, but patients will eventually be symptomatic because of the development of congestive failure as well as angina. Sudden death may occur. Signs of a poor prognosis include severe aortic valve disease, resistant anginal pains, resistant left ventricular failure, and frequent ventricular arrhythmias.

Diagnosis and Differential Diagnosis

The diagnosis of aortic insufficiency is usually not difficult if the characteristic murmur is detected. The most common reason for missing the diagnosis is failure to perform a careful, systematic examination in a quiet atmosphere. Once the characteristic murmur is heard, it has to be differentiated from other causes of left parasternal diastolic murmurs such as Graham Steell's murmur. The latter is a soft early diastolic left parasternal murmur resulting from functional pulmonary incompetence secondary to dilatation of the pulmonary artery as a result of severe pulmonary hypertension. If the systemic arterial pulse pressure is wide and the diastolic pressure is low, aortic insufficiency is likely to be the cause of the murmur. The murmur of pulmonary insufficiency is usually not heard to the right of the sternum, whereas the murmur of aortic insufficiency, although louder to the left of the sternum, is usually well heard also to the right. Graham Steell's murmur is associated with the clinical and laboratory manifestations of pulmonary hypertension. Doppler echocardiography is a very sensitive tool in differentiation between pulmonary and aortic insufficiency.

Aortic insufficiency also has to be differentiated from other causes of aortic runoff including patent ductus arteriosus, ruptured sinus of Valsalva, coronary arteriovenous fistula, and aortic–left ventricular tunnel.

Once the diagnosis of aortic valve disease has been established, it is important to establish the etiology. A history of rheumatic fever and/or evidence of organic mitral valve disease favors rheumatic etiology. If there is evidence of associated significant aortic stenosis (supravalvular, valvular, or discrete subvalvular), the cause of aortic insufficiency is usually congenital. Isolated congenital aortic insufficiency is very rare and can occur with aneurysms of the sinus of Valvalva. Other causes of aortic insufficiency at a young age include aortic insufficiency that occurs with coarctation of the aorta, ventricular septal defect, and Marfan's syndrome.

An important differential diagnosis is infective endocarditis on a congenitally deformed aortic valve. This will lead to combined aortic stenosis and insufficiency. Differentiation between infective endocarditis and rheumatic fever is described in the Chapter 86 on rheumatic fever.

RHEUMATIC TRICUSPID VALVE DISEASE

Rheumatic tricuspid valve disease is almost invariably associated with mitral or aortic valve disease. While very few cases of isolated rheumatic tricuspid stenosis have been reported,[86] isolated incompetence has not been described.[87]

The incidence of tricuspid valve disease differs according to the criteria involved, whether clinical and hemodynamic or pathologic and surgical. Microscopic evidence of rheumatic inflammation of the tricuspid valve has been found as often as in the mitral valve, but significant clinical regurgitation or stenosis is far less common. The incidence of clinical tricuspid disease now is greater than was recognized previously; there is now increased awareness, more precise diagnosis, and, most important, routine exploration of the tricuspid valve at the time of operation for mitral valve disease. Tricuspid valve disease was noticed in about 30% of patients operated on for mitral valve disease in areas where rheumatic heart disease is prevalent; half of these cases required correction.[88,89]

Pathology

Organic Tricuspid Stenosis

Tricuspid stenosis is present on pathologic examination in 5 to 10% of patients with rheumatic heart disease and is always associated with more severe mitral valve disease.[90,91] It is a consequence of rheumatic valvulitis, which causes inflammation and scarring, leading to commissure fusion with narrowing of the orifice area. Leaflet and chordal thickening sometimes occur but with much less extent.

Organic Tricuspid Incompetence

Organic tricuspid incompetence can occur either alone or with organic tricuspid stenosis as a result of rigidity of orifice edges, shrinkage of leaflet tissue, annular dilatation, or a combination of these abnormalities.

Functional Tricuspid Incompetence

Functional tricuspid incompetence occurs because of annular dilation and malalignment of papillary muscles due to right ventricular failure complicating pulmonary hypertension or loss of contraction of the tricuspid annulus during atrial fibrillation.[90] Anatomic studies proved that annular dilatation is asymmetrical, affecting the posterior and anterior leaflets and commissured areas and sparing the septal side of the annulus.[92] Partial tilting of the ring was proposed as a mechanism of functional tricuspid incompetence leading to a gap between the septal leaflet and the anterior and posterior leaflets.[89]

Pathophysiology

Tricuspid incompetence permits blood to regurgitate into the right atrium, leading to initial diminution of the forward flow by the same amount. The larger volume of blood in the right atrium increases the pressure of the v wave so that when the right ventricle relaxes, it becomes subjected to higher filling pressure and dilates more to accommodate this extra blood. In this sense, augmented diastolic filling will compensate for the leak. Right ventricular dilation will intensify the leak and magnify the heart failure. So tricuspid incompetence may both augment and be augmented by congestive heart failure. Myocardial resistance and a restraining effect of the pericardium act in the opposite direction to stop this vicious circle.

As regards tricuspid stenosis, its cardinal feature is a diastolic pressure gradient across the tricuspid valve with elevation of right atrial pressure. This gradient varies with heart rate, cardiac output, exercise, and respiration. It is marked in presystole in sinus rhythm, and in early diastole in atrial fibrillation.[93] If tricuspid stenosis is suspected, the gradient must be measured between the right atrium and right ventricle simultaneously.[94]

Symptoms

Symptoms of pulmonary congestion are less common and less severe in patients with predominant tricuspid stenosis than in those with predominant incompetence. This is because of the reduced right ventricular filling secondary to obstruction of blood flow.

However, symptoms are dominated by the associated more severe left-sided lesions.

General Examination

General signs are caused by elevated systemic venous pressure due to either tricuspid valve obstruction or incompetence. With tricuspid incompetence, there is a prominent systolic CV wave in the jugular venous pulse and rapid Y descent. With tricuspid stenosis, there is a brief, sharp, tall a wave; there is a flickering a wave in patients with sinus rhythm. In both conditions, the liver is enlarged and tender. There may be edema, ascites, and sometimes protein-losing enteropathy. Systolic pulsation may be noticed in most patients with significant tricuspid incompetence. Liver congestion commonly leads to impaired liver function with elevated serum bilirubin and mild icterus, giving the patient a characteristic appearance. There may be cold hands with peripheral cyanosis because of low cardiac output.

Auscultation

The murmur of tricuspid incompetence is audible at the lower left sternal border, is pansystolic and usually followed by a third sound, and may radiate to the apex. Inspiration may increase the intensity of the murmur and may also change its character. This murmur is inconstant and may vary from day to day in its intensity.[95]

The diastolic murmur of tricuspid stenosis mimics that of mitral stenosis. However, it is usually best heard at the lower left sternal border and has a higher pitch than that of mitral stenosis. A tricuspid opening snap may be audible.

Generally, tricuspid murmurs tend to increase with inspiration, but this is usually difficult to elicit in many patients because of gross heart failure. Also, lung expansion during inspiration interferes with auscultation.

The clinical diagnosis of tricuspid stenosis may be difficult. The available signs—flickering a wave (rapid rise and slow descent), inspiratory increase of diastolic murmur, and right atrial enlargement—all give presumptive evidence of tricuspid valve disease. Despite the greater ease in diagnosing tricuspid incompetence, there is no pathognomonic sign.

Electrocardiography

Electrocardiogram changes with tricuspid incompetence are nonspecific. There may be evidence of right atrial enlargement and right ventricular hypertrophy. Atrial fibrillation is present in most of these patients. Tricuspid stenosis is suggested in the presence of a tall, peaked P wave with a long PR interval without right ventricular preponderance.

Roentgenography

In tricuspid stenosis, right atrial enlargement may be out of proportion to pulmonary hypertension. No correlation has been found between the right atrial enlargement and C/T ratio and the severity of tricuspid valve disease.

Echocardiography

M-Mode Echocardiography

The normal tricuspid valve M-mode echocardiogram has a pattern of motion similar to that of the mitral valve. However, in normal subjects, it is usually difficult to record the entire motion of the tricuspid valve. The tricuspid valve is recorded easily only if there is right ventricular enlargement.[96]

The criteria used to diagnose tricuspid stenosis on an M-mode echocardiogram include a diminished EF slope, anterior displacement of the posterior tricuspid leaflet, and thickening of the valve.[97] However, there are problems with each of these criteria. In rheumatic heart disease, there is often concomitant pulmonary hypertension and right ventricular hypertrophy secondary to mitral valve disease. This may diminish the tricuspid EF slope,[98] but if the reduced EF slope is associated with a reduced DE amplitude of excursion (less than or equal to 10 mm), the diagnosis of tricuspid stenosis is more likely.[99] The anterior displacement of the posterior leaflet of the tricuspid valve cannot always be detected; therefore, when it is absent, tricuspid stenosis cannot be excluded.[98] Thickening of the cusps indicates a diseased valve that is not necessarily stenotic.[99]

Two-Dimensional Echocardiography

There is no specific picture for diagnosis of tricuspid insufficiency by two-dimensional echocardiography. "Tricuspid leaflet thickening, doming of the valve, and restricted leaflet motion" were found in each of four cases with hemodynamic evidence of tricuspid stenosis in a series of 100 patients with rheumatic heart disease.[98] Similar findings were not present in any of the remaining 96 patients who did not have tricuspid valve gradients. The reported sensitivity and specificity for the two-dimensional echocardiogram study in the diagnosis of tricuspid stenosis were both 100%. Another study[100] reported a sensitivity and a specificity of 69% and 96%, respectively, in a group of 38 patients who had both echocardiographic and hemodynamic evaluation.

Contrast Echocardiography

Contrast echocardiography done by rapid injection of saline into the antecubital vein is a very sensitive tool for detecting tricuspid incompetence.[101] However, it yields false-positive results in 10% of cases with a predictive value of 90% and is considered a good negative test to exclude tricuspid incompetence.[89] In terms of positive results, microcavitation can be seen moving back and forth across the tricuspid valve and can be seen in the inferior vena cava and hepatic vein during systole.

Doppler Echocardiography

Doppler echocardiography is the most reliable noninvasive method for assessing the severity of tricuspid regurgitation, and it is useful even in patients with atrial fibrillation, congestive heart failure, or right ventricular pressure overload.[102] Doppler echocardiography has shown the low sensitivity of clinical diagnosis of tricuspid regurgitation.

In 1982, Miyatake and colleagues[103] reported pansystolic abnormal Doppler signals in the right atrial cavity in 58 of 62 patients with suspected tricuspid regurgitation. The tricuspid regurgitation was graded on a scale of 1 to 4+ on the basis of the distance traveled by the abnormal signals from the tricuspid orifice toward the posterior right atrial wall. The right ventriculograms were also graded on a four-point scale. Grades matched exactly in 36 patients but differed by one point in 23 patients and by two points in 3 patients.

A noninvasive estimate of right ventricular systolic pressure can

be obtained by Doppler by calculating the pressure gradient between the right ventricle and the right atrium in systole from the maximal velocity jet in tricuspid regurgitation.[25]

The presence of tricuspid stenosis is easy to diagnose with Doppler ultrasound, and the pressure drop calculated from the maximal velocity seems so far to correlate well with the pressure drop obtained by catheter withdrawal from the right ventricle to the right atrium.[25,104]

Hemodynamics and Angiographic Studies

In tricuspid insufficiency, the right atrial and right ventricular end-diastolic pressures are elevated. The right atrial pressure shows an absence of X descent and a prominent CV wave. In severe cases, there is ventricularization of right atrial pressure. Right ventricular angiography is not a good method to diagnose and assess the degree of tricuspid incompetence, since the catheter across the tricuspid valve may induce incompetence, leading to a false-positive result. However, there are some claims that this method can be used to evaluate tricuspid incompetence.[105]

Cardiac catheterization provides the most reliable means of quantifying the degree of tricuspid stenosis. A small diastolic gradient of 2 mm Hg across the tricuspid valve is sufficient to establish diagnosis, and a gradient of 5 mm Hg implies significant stenosis sufficient to produce systemic venous congestion. This gradient is presystolic in sinus rhythm and early diastolic in atrial fibrillation. If tricuspid stenosis is suspected, right atrial and ventricular diastolic pressure should be recorded simultaneously. However, rarely, significant tricuspid stenosis may not be associated with a diastolic gradient.[106] Right atrial angiography in a 30% right anterior oblique position demonstrates a characteristic doming of a tricuspid valve and delayed emptying of the right atrium, ejecting blood across a funnel-shaped tricuspid valve (Fig. 87–22).

TREATMENT OF RHEUMATIC HEART DISEASE

Prophylaxis

Treatment includes prophylaxis against rheumatic fever and its recurrences and against the occurrence of infective endocarditis.

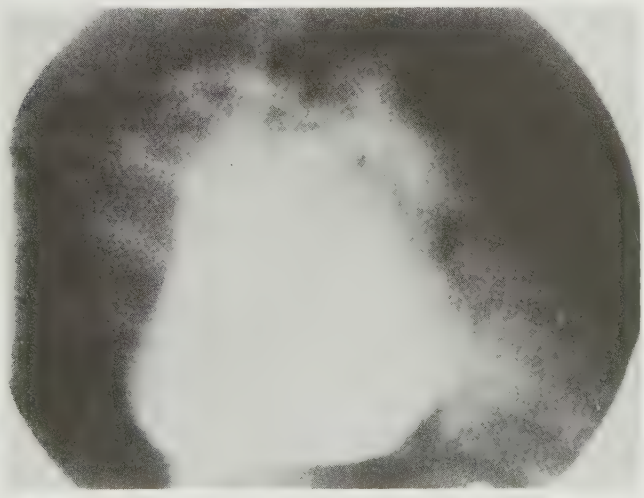

Fig. 87–22. Right atrial angiography in a patient with tricuspid stenosis showing markedly dilated right atrium with delayed emptying as well as funnel-shaped stenosed tricuspid valve.

Since rheumatic fever is linked to an antecedent group A beta-hemolytic streptococcal infection, prophylaxis is directed against streptococcal infections. The preferred form of continuous prophylaxis is the monthly intramuscular injection of 1,200,000 units of benzathine penicillin. If the patient is allergic to penicillin, oral erythromycin twice daily should be used. Although the American Heart Association recommends that penicillin prophylaxis be continued for life,[107] most cardiologists tend to discontinue rheumatic fever prophylaxis by the time the patient has reached age 50 in Western countries and age 25 in Eastern countries unless there have been attacks of acute rheumatic fever within the previous five to ten years.

Antibacterial prophylaxis for prevention of infective endocarditis should be used for all dental procedures, including filling and cleaning of teeth[108] as well as dental extractions. Prophylaxis should also be used in the event of other exposures to bacteremia, including genitourinary and gastroenterological surgical procedures.

Physical Activity

In asymptomatic patients with mild-to-moderate valvular disease with normal heart size or insignificant cardiomegaly, normal school activity should be encouraged. Restriction of activity is unnecessary and may be harmful. In symptomatic patients, the allowed activity should be the one that does not produce symptoms of fatigue, dyspnea, or excessive palpitation. Weight lifting and other isometric exercises should be discouraged. Competitive sports are not generally recommended, since the patient may tend to ignore symptoms in the excitement of a contest.

Management and Complications

Anemia and Infections

Patients with chronic rheumatic heart disease generally have diminished cardiac reserve. Cardiac decompensation can be precipitated by anemia and/or minor infections; therefore such factors should be treated both promptly and aggressively. Chest infections are often precipitated by fluid retention, so a diuretic is usually needed.

Arrhythmias

In rheumatic mitral valve disease, frequent premature atrial contractions often presage atrial fibrillation, and the administration of antiarrhythmic drugs may be effective in preventing this complication. Atrial fibrillation, flutter, and tachycardia can complicate such cases. The immediate treatment should be directed toward reducing the ventricular rate and, if possible, toward reestablishing sinus rhythm by pharmacologic treatment and cardioversion singly or in combination. Following reversion to sinus rhythm, administration of quinidine or a similar antiarrhythmic agent should be continued indefinitely to diminish the likelihood of recurrence.

Patients with significant mitral valve disease, hugely dilated left atria, and chronic atrial fibrillation (for six months or longer) who cannot be converted or maintained in sinus rhythm (including a trial of amiodarone) should receive adequate doses of digitalis to keep the ventricular rate at rest at approximately 60 to 65 beats per minute. If this is not feasible, small doses of a beta blocker or the slow channel calcium blocker verapamil may be added if the ventricular function is normal.

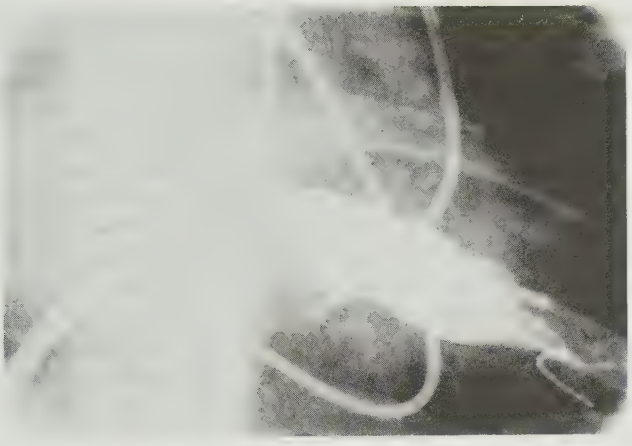

Fig. 87–23. Roentgenogram showing two inflated balloons across the mitral valve. Both were passed along wires after transseptal catheters.

Thromboembolism

As a general rule, anticoagulant therapy should be given to reduce the risk of embolism to all patients with atrial fibrillation unless there are very strong contraindications.

If an operation is not to be carried out, oral anticoagulants should be administered to patients with mitral valve disease who have suffered systemic emboli as well as patients who are at high risk of embolization, that is, those who are in atrial fibrillation, have greatly enlarged left atrium, and/or have a left atrial thrombus demonstrated by two-dimensional echocardiography.

Infective Endocarditis

Infective endocarditis is treated in the usual way.

Heart Failure

It is desirable to administer digitalis to patients with significant valvular lesions who begin to develop effort fatigue or dyspnea, with or without frank evidence of left or right heart failure. However, if a patient with isolated mitral stenosis does not have either right heart failure or atrial fibrillation or flutter, little hemodynamic benefit can be expected from the use of digitalis.[109] Fluid retention in such conditions responds well to treatment with diuretics. In addition, a low-sodium diet is advisable, especially if the diuretics are not completely effective. It should be emphasized that the measures designed to reduce pulmonary venous pressure, including sedation, assumption of upright posture, and aggressive diuresis are also used to treat hemoptysis of lung congestion.

Patients with frank cardiac failure are treated in the usual way. Uncontrollable heart failure in children must raise the possibility of severe valvular afflictions, rheumatic activity, infective endocarditis, or electrolyte imbalance.

The response to vasodilator therapy is impressive in cases of mitral and aortic insufficiency. Hemodynamic studies have shown beneficial effects of intravenous hydralazine[110] and oral prazosin.[111] This therapy may be helpful in stabilizing patients who are waiting for surgery. Moreover, agents such as nitroglycerine given sublingually may be effective in relieving dyspnea brought on by exercise and permit the same exercise to be taken with a lower pulmonary artery pressure by causing venous dilatation, arteriolar dilatation, or both.

Catheter Balloon Valvuloplasty

Dilatation of stenosed mitral valves by balloon valvuloplasty catheters is emerging as a successful way of relieving mitral obstruction[112,113] (Fig. 87–23). This procedure is currently used in patients with sinus rhythm who have pliable mitral noncalcified leaflets and do not have left atrial thrombi. Dilatation of tricuspid stenosis has also proved very helpful in some patients[114] (Fig. 87–24). This technique would be ideal in children, who have pliable noncalcified leaflets, to avoid thoracotomy.

Surgical Treatment

Although the only direct therapy of cardiac valve disease is surgical, management of children with this illness should conserve the natural valve whenever possible. There is no prosthesis that is totally free of thromboembolic and anticoagulation problems and that has an effective orifice that will not be outgrown by a small child.

Currently, available tissue heterografts are prone to calcification and early tissue failure in the aortic and mitral positions and cannot be recommended in children except under unusual circumstances. Tissue valves continue to be the valves of choice for the tricuspid and pulmonary positions.

On the basis of our current knowledge, it is recommended that mechanical aortic and mitral valves be used for children (Fig.

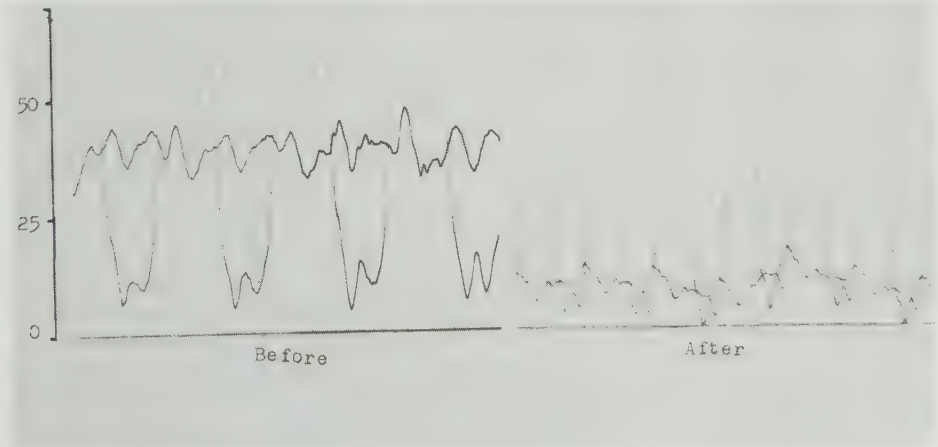

Fig. 87–24. Tracing on left demonstrating 30 mm Hg diastolic gradient from LA–LV; in tracing on right, after balloon mitral valvuloplasty gradient is essentially eliminated. Shows a drop in the left atrium–left ventricle diastolic gradient by balloon mitral valvuloplasty.

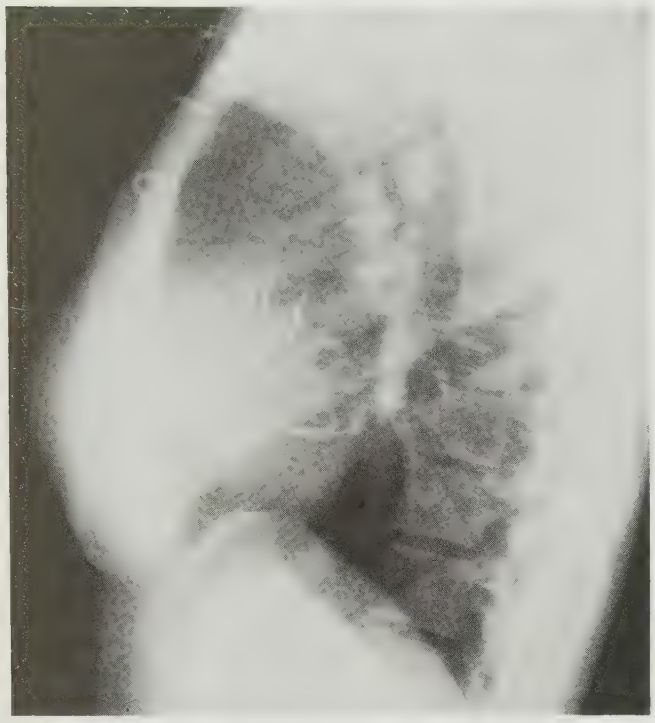

Fig. 87–25. Lateral chest radiograph showing the stents of mitral and aortic valves placed at a young age.

87–25). It is also recommended that anticoagulant therapy be used with all types of mechanical valve prostheses, even though the incidence of thromboemboli is much lower in children than in adults.

The durability of recently introduced mechanical valves seems superior to that of certain previously introduced ones, but many more years of followup will be required to substantiate this alleged superiority.[115] Also, the modification of tissue valve fixation using low pressure instead of high pressure and the addition of anticalcification agents to tissue valves may improve their durability.[115]

We now turn to the particular problems associated with valve replacement in the pediatric age group.

Surgical Treatment of Mitral Stenosis

Mitral stenosis causes mechanical obstruction to the circulation, and the most satisfactory treatment is opening the obstruction. A number of procedures are available, including open or closed mitral valvotomy, mitral valve replacement, and balloon dilation. The choice depends on the anatomy of the mitral valve determined by assessment of the physical signs, echocardiogram, age of the patient, and resources available.

The decision about the first operation is an important one, since it represents the initial stage in the lifetime care of the patient's mitral valve. Closed mitral valvotomy is a relatively simple procedure in terms of the resources that are required, although a satisfactory result presupposes considerable surgical expertise. It is particularly suitable in a young patient in sinus rhythm with evidence of a mobile anterior cusp.

Open valvotomy requires cardiopulmonary bypass but allows a more complete procedure to be undertaken and, in particular, allows the subvalvular apparatus to be inspected and adherent chordae to be divided. If the results of valvotomy are found to be unsatisfactory, then it is possible to proceed to valve replacement in the same operation. If the valve cusps are greatly thickened or calcified, then mitral valve replacement is required. This operation should not be considered for patients in whom the hemodynamic disturbance caused by the valve disease is mild, since resting diastolic pressure gradients and abnormal left ventricular filling can be demonstrated with all currently available mitral prostheses.

In summary, if the clinical evidence suggests that a valvotomy is feasible, then the presence of definite limitation of exercise tolerance is an adequate indication, particularly in a young person. If valve replacement is likely to be required, the decision to operate requires more severe symptoms.

Timing of Surgery in Chronic Mitral and Aortic Insufficiency

Chronic mitral and aortic insufficiency share the same physiologic and clinical features. Both valvular lesions impose a volume load on the left ventricle, leading to chamber dilatation and myocardial hypertrophy. The natural history of both lesions is characterized by a long asymptomatic period; and when congestive heart failure develops, valve replacement is effective in alleviating symptoms. At the same time, myocardial dysfunction initially occurs at a subclinical level in both conditions and may become irreversible before symptoms of congestive heart failure develop.[116]

The timing of surgery for these two conditions is controversial. Because it is difficult to predict the onset of left ventricular dysfunction, arguments have been made in support of early surgery even in the absence of symptoms.[117,118] The arguments for early intervention have been disputed on the basis of operative mortality and prosthesis complications[119] as well as the relatively benign natural history of patients who remain asymptomatic.[120] At the same time, delay in performing surgery when left ventricular dysfunction is severe is associated with higher operative mortality and poor postoperative course.

Surgery for chronic rheumatic mitral or aortic insufficiency is clearly indicated in patients who have significant functional limitations, since valve replacement usually improves symptoms. However, functional class IV is associated with high operative mortality and poor long-term survival after valve replacement.

Because surgery is unwarranted in asymptomatic patients with normal ventricular function and may be of marginal benefit in severely symptomatic (functional class IV) patients, the question arises as to the time for surgery. The suggested approach for mitral insufficiency and for aortic insufficiency depends on multiple clinical, echocardiographic, and hemodynamic predictions of left ventricular function.

1. All patients with functional class III or IV congestive heart failure should have mitral valve replacement or aortic valve replacement.
2. All asymptomatic or mildly symptomatic patients should be evaluated for possible surgery. If the valve lesion is severe and there is evidence of left ventricular dysfunction, surgery must be considered. If the left ventricular function is normal, it may be appropriate to follow the patients. Any evidence of left ventricular dysfunction is an indication for surgery.

Surgery of Rheumatic Tricuspid Valve Disease

There is still controversy as to whether the decision to correct a tricuspid valve lesion can be made preoperatively. Some believe that the assessment can be made accurately by hemodynamic and angiographic studies.[121–123] Others believe that finger exploration before cardiopulmonary bypass is mandatory to assess the valve function in patients subjected to mitral or aortic valve surgery.

Until recently, management of tricuspid incompetence has also been controversial. Some have advocated conservative management, others have advised replacement,[124] and some have recommended repair.[125] It has been found that the presence of tricuspid valve disease seriously compromised the results of operations for mitral valve disease.[122] Tricuspid valve replacement is rarely performed because no valve has proven ideal.[126] The majority of cases with tricuspid incompetence can be corrected by valve reconstruction. Even mild tricuspid incompetence should be corrected during initial operation for associated valve lesions because of the unpredictability of the course in these patients.

DeVaga semicircular suture annuloplasty and Carpentier flexible ring have offered excellent solutions for the problem of tricuspid incompetence.[127,128]

As regards tricuspid stenosis, open tricuspid commissurotomy has become the procedure of choice, since it offers complete and safe correction of the stenosed valve.[129]

Problems Associated with Valve Replacement

In areas where rheumatic fever is prevalent and severe, valvular damage may necessitate early surgery in increasing numbers of patients. Valve replacement in this age group is plagued by a myriad of problems in the preoperative, intraoperative, and postoperative phases (Table 87–1).

Preoperative Problems

Rheumatic activity can be lingering and sometimes almost continuous.[130] Children with chronic rheumatic activity and severe valvular damage may have to undergo surgery without waiting for quiescence of activity. The impact of this on long-term survival has not been studied.

Table 87–1. Problems Associated with Valve Replacement in the Pediatric Age Group

Problems in the preoperative period:
Persistent rheumatic activity
Lack of compliance with treatment
Choice of prosthesis
Intraoperative problems:
Small annulus
Small ventricular cavity
Damage to conduction system
Postoperative problems:
Difficulties with anticoagulation
Recurrence of rheumatic activity
Prosthesis malfunction caused by small ventricular cavity
Ventricular dysfunction caused by large prosthesis size
Problems with reoperation:
Higher morbidity and mortality of redo surgery in general
Small annulus
Coronary ostial stenosis (?)

Most youngsters comply poorly with long-term medication, diet, and effort restriction and may thus have to undergo surgery in a less than optimal condition.

The choice of prothesis in this age group is a real dilemma.[131–133] Caged ball valves are too bulky for small cardiac chambers, and the hydrodynamic characteristics of small sizes are poor. Tilting disc valves, on the other hand, are less bulky, but their excursions are often limited by small chamber size, leading to stenosis, incompetence, and increased thrombogenicity because of stasis.[134] Bioprosthetic valves have high failure rates, particularly in young patients. Failures may be the result of dissolution of collagen, thrombosis, calcification, or a subtle form of graft rejection.[135–137] Promising results have recently been obtained with developments in artificial valve technology. The most prominent of these is the development of third-generation (supra-annular) Carpentier-Edwards valves,[138] the monostrut Bjork-Shiley valve,[139] the Medtronic-Hall valve,[140] and the St. Jude valve. These prostheses have a low gradient even with small sizes and are thus of potential benefit in pediatric valve replacement.

Intraoperative Problems

The implantation of a relatively large valve may be difficult because of a small annulus, more commonly so in the aortic position. Several procedures have been tried to enlarge the left ventricular outflow tract. The most commonly used is the Konno procedure, in which the aortic annulus is divided, the ventricular septum is incised, and the anterior mitral leaflet is incised to provide space for valve implantation.[141,142] This procedure may damage the conduction system, create mitral incompetence, and render further reoperation technically difficult.

As was mentioned earlier, the left ventricular outflow tract may be too small for the implantation of a caged ball prosthesis in the mitral position.

Postoperative Problems

Compliance of young patients with long-term anticoagulant therapy is poor.[143] On the other hand, the more vigorous life they lead makes them more liable to trauma and serious hemorrhage when on anticoagulant therapy. The use of platelet aggregation inhibitors[144,145] and pentoxifylline[146] is currently under trial.

Recurrence of rheumatic activity can still be encountered after valve replacement in this age group. The subsequent further valvular and/or myocardial damage can alter the prognosis and make further surgery more risky or less useful.

Prosthesis malfunction caused by a small ventricular cavity may lead to limited excursions with subsequent prosthesis stenosis, incompetence, and stasis, leading to increased thrombogenicity.

Of equal importance is poor ventricular performance caused by a large prosthesis in the ventricular cavity. Ventricular dysfunction is probably caused by (1) mechanical interference with ventricular emptying, (2) loss of papillary muscles, and (3) lack of the normal contraction of the mitral (or tricuspid) annulus during ventricular evacuation, that is, loss of annulus function.[147]

There are no data to indicate whether young patients with artificial heart valves are more prone to infective endocarditis than older patients. The same applies to prosthesis-induced hemolysis.

Problems with Reoperation

Valves implanted before the rapid growth phase of adolescence will invariably need to be replaced during adulthood because of

disparity of valve size and the need for increased cardiac output. Apart from the increased mortality and morbidity of redo surgery in general, the aortic and/or mitral annulus may, at the time of reoperation, be too small for the now-appropriate prosthesis size. Annulus enlarging procedures (e.g., Konno) or left ventricular apicoaortic conduits[148] may be required.

CHAPTER 88

Cardiovascular Manifestations of Connective Tissue Diseases

Karyl S Barron

Connective tissue disease is a term used to describe any one of many disorders of uncertain cause, which have overlapping clinical manifestations and may share common mechanisms of pathogenesis. This chapter deals with the more common connective-tissue diseases of childhood, including juvenile rheumatoid arthritis, systemic lupus erythematosus, drug-induced lupus, neonatal lupus, the spondyloarthropathies (including juvenile ankylosing spondylitis, Reiter's syndrome, and arthritis associated with inflammatory bowel disease), and Lyme disease. The most apparent clinical symptoms involve the joints and skin; however, each of the diseases may have a systemic component that affects the cardiovascular system. The spectrum of cardiac involvement includes pericarditis, myocarditis, endocarditis, coronary artery disease, systemic arteritis, pulmonary hypertension, and conduction system abnormalities.

JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis (JRA) is the most common pediatric connective-tissue disease. The following classification enumerates the requirements for a diagnosis of JRA and the three clinical onset subtypes.[1] By definition, JRA begins before the age of 16 years. Persistent arthritis of one or more joints of at least 6 weeks' duration is sufficient for diagnosis if other causes of arthritis are excluded. Arthritis is defined as swelling of a joint or limitation of joint motion, with heat, pain, or tenderness. Pain or tenderness alone is not sufficient for the diagnosis of arthritis.

The onset subtype is determined by manifestations that occur during the first 6 months of disease. Systemic-onset JRA is defined as JRA with persistent intermittent fever (daily intermittent temperatures of 103°F or more) with or without rheumatoid rash or other organ involvement. Typical fever and rash are considered *probable* systemic-onset JRA if they are not associated with arthritis; however, before a definite diagnosis can be made, arthritis, as defined above, must be present. Children with systemic-onset JRA make up 10 to 30% of the cases of JRA. The sex ratio is equal or with a slight male preponderance. In addition to the fever and rash, extra-articular findings may include hepatomegaly, splenomegaly, generalized lymphadenopathy, pericarditis, pleuritis, and nonspecific abdominal pain. The laboratory findings in the classic picture include anemia, leukocytosis, and an elevated sedimentation rate. Antinuclear antibodies, rheumatoid factor, and HLA-B27 are usually negative. Approximately 40% of these patients will develop evidence of severe, progressive joint disease.[2]

Pauciarticular-onset JRA is defined as JRA with arthritis involving four or fewer joints; it accounts for 40 to 50% of JRA cases. Patients with systemic-onset JRA are excluded from this onset group. Within this group there are three different subtypes. Subtype I occurs predominantly in girls (female:male ratio, 6:1); onset is typically in early childhood, and at some point iritis develops.[2] Antinuclear antibodies are usually positive in this subgroup.[3] The iridocyclitis occasionally precedes joint complaints, but more often occurs at the onset of joint symptoms or during the course of the disease. The iridocyclitis is often chronic and insidious with great potential for ocular damage. Subtype II typically occurs in older boys (male:female ratio, 9:1) with lower extremity arthritis. Rheumatoid factor and antinuclear antibodies are often negative. More than half these patients are positive for HLA-B27.[4,5] These children often later develop sacroiliitis. In the

second or third decade of life, when sacroiliac or lumbar arthritis becomes apparent, patients with this subtype may fulfill the criteria for ankylosing spondylitis or another of the spondyloarthropathies. Subtype III of pauciarticular-onset JRA involves children with arthritis in four or fewer joints who do not develop either iritis or sacroiliitis.

Polyarticular-onset JRA is characterized by the presence of arthritis in five or more joints, and occurs in approximately 40 to 45% of children with JRA. There is a female preponderance. The majority of children with polyarthritis have negative results for rheumatoid factor. A subgroup of patients will have positive rheumatoid factors. Those with positive rheumatoid factors are more likely to develop severe chronic arthritis and therefore have a worse prognosis than those who are rheumatoid factor–negative. The subgroup with positive rheumatoid factors closely resembles classic adult-onset rheumatoid arthritis.

Cardiovascular Manifestations of JRA

Pericarditis

The principal cardiac findings in children with JRA relate to pericarditis, ranging from completely asymptomatic patients with echocardiographic findings of minimal pericardial effusions to patients with severe life-threatening cardiac tamponade. Before the availability of the echocardiogram, pericarditis was recognized clinically in approximately 10% of children with JRA.[6] Autopsy reports, however, have revealed an incidence of pericarditis as high as 45%.[7] In a study by Lietman and Bywaters, the pericarditis was unrecognized clinically in the majority of patients.[7] With the advent of echocardiography, more accurate assessment of the incidence of pericarditis in JRA is available. Bernstein et al.[8] obtained echocardiograms, ECG, and chest radiographs from 55 patients with JRA. Twenty (36%) had echocardiographic evidence of pericarditis. Of these patients, ECGs were normal in 12 and abnormal in eight. Cardiac size by chest radiograph was normal in 11, with cardiac enlargement in nine. In at least 11 of the 20 patients with a positive echocardiogram, the diagnosis of pericarditis was not otherwise apparent. Other studies have revealed a lower incidence of pericarditis. Brewer[9] obtained echocardiograms from 50 consecutive patients with JRA. Of these 50, 45 were normal and had no clinical symptoms of pericarditis, three were clinically ill with pericarditis and had echocardiographic evidence of pericardial effusions, and two patients had minimal pericardial effusions without clinical findings suggestive of pericarditis.

The occurrence of pericarditis may occasionally precede the onset of arthritis, but this is unusual. Some patients have pericarditis at the time of disease onset, but the majority develop clinically apparent pericarditis several months or even years after the onset of arthritis.[2,7] Pericarditis occurs more often in patients with systemic-onset disease than in patients with polyarticular- or pauciarticular-onset disease,[7–9] and frequently accompanies a flare of systemic symptoms, especially fever. Patients with pericarditis are more likely to have a rash, lymphadenopathy, splenomegaly, pulmonary disease, or amyloidosis than patients without pericarditis.[7] They are also more likely to have lower hemoglobin levels, higher white blood cell counts, and higher sedimentation rates than patients without pericarditis.[8]

Clinical Presentation of Pericarditis. Brewer et al.[2] have divided the clinical presentation of pericarditis into the following groups.

Subclinical Pericarditis. The advent of echocardiography has made apparent that there is a group of patients with echocardiographic evidence of pericardial effusions who have a normal physical exam, chest radiograph, and ECG.[8,9] Precordial pain and dyspnea are frequently absent in the JRA patient with pericarditis; most attacks of pericarditis remain asymptomatic and undetected.[10] Consequently, clinicians should suspect pericarditis in all patients with prominent systemic manifestations. The child should be examined regularly for the appearance of a friction rub, pulsus paradoxus, or cardiomegaly, and screened intermittently for abnormalities on ECG and echocardiogram. In most cases, the pericarditis will resolve spontaneously.

Mild Pericarditis. Mild pericarditis is characterized by an intermittent or constant friction rub with mild cardiac enlargement on chest radiograph.[2] Patients with this condition may demonstrate tachycardia and nonspecific ECG changes. These patients are usually minimally symptomatic, but occasionally will complain of mild shortness of breath or minimal chest pain with exertion. The episode often subsides spontaneously.

Moderately Severe Pericarditis. Patients with moderately severe pericarditis often complain of chest pain aggravated on assumption of the supine position and worsened with deep inspiration. Pericardial friction rubs, tachycardia, and tachypnea or dyspnea are common. A typical episode may last for weeks or months with periodic exacerbations and partial remissions.

Severe Pericarditis with Cardiac Tamponade. Cardiac tamponade secondary to severe pericarditis is an extremely uncommon complication of JRA. In their series of 55 patients with JRA and cardiac involvement, Bernstein et al.[8] had no patients with tamponade. Schaller and Wedgewood[11] reported only two cases of severe pericarditis in a review of 124 JRA patients, and no patient had tamponade. The literature contains only a few documented cases of cardiac tamponade related to JRA.[6,12–14] In these reports, the tamponade occurred only in children experiencing significant systemic flare-up of their JRA, and was accompanied by high fever, hepatomegaly, and arthritis. In one series,[6] two of three patients had been treated with phenytoin prior to the onset of cardiac involvement and the authors speculated that this medication may predispose children with systemic JRA to develop severe pericarditis and tamponade. In some of the patients cited in the literature, pericardiocentesis revealed a serosanguineous fluid with a neutrophilic pleocytosis, diminished concentrations of glucose and hemolytic complement, high levels of acid phosphatase and lactic dehydrogenase, and the absence of rheumatoid factor.[12,13] Obtaining these laboratory parameters may help in distinguishing the pericarditis of JRA from infectious pericarditis occurring in a JRA patient. Constrictive pericarditis has not been reported as a longterm complication of severe pericarditis in JRA patients.

Treatment of Pericarditis. Treatment of pericarditis in JRA varies depending upon the severity of clinical involvement. Asymptomatic or mild pericarditis requires no additional therapy. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be adequate in the treatment of moderately severe pericarditis; however, some patients may require short courses of corticosteroid therapy. Treatment of severe pericarditis is generally the same as that for severe systemic JRA. Prednisone (1–2 mg/kg/day), or an equivalent drug, or high-dose pulse steroid therapy may decrease the associated

morbidity and also decrease the necessity of pericardiocentesis. Because of the rarity of tamponade, the best method of managing it is difficult to decide. Pericardiocentesis may be therapeutic in the presence of significant or progressive compromise of cardiac function. Diagnostic pericardiocentesis is occasionally required if an infectious pericarditis is suspected. One child was treated by pericardiocentesis and local corticosteroid injections,[12] while others have been treated with pericardiocentesis and systemic corticosteroids.[6,13]

Myocarditis

Myocarditis occurs much less frequently in the setting of JRA than does pericarditis, and few cases have been cited in the literature.[10,15–17] Bernstein et al.[8] have suggested that myocarditis may be present in as many as 10% of JRA patients. In that study, four of 40 JRA patients in whom systolic time intervals were studied had prolongation of the left ventricular pre-ejection period, suggesting decreased ventricular performance possibly indicating myocarditis.

Clinical Presentation of Myocarditis. Myocarditis usually occurs in a background of severe active systemic-onset JRA, and often recurs with flare-ups of systemic disease.[10,15,16] This situation is also the one in which pericarditis is most common, so that myocardial disease may be masked. Clues to impending myocarditis include the appearance of cardiomegaly and/or congestive heart failure (CHF) in the absence of substantial pericardial effusion; reduced ventricular function and/or cardiac dilation on echocardiogram; the appearance of sinus tachycardia inconsistent with the degree of fever or anemia present; tachypnea; changing heart sounds; arrhythmias; and the coexistence of pleuritis and/or pneumonitis.[10,15] The cause of the myocarditis in JRA is unknown. Its appearance with flare-ups of systemic disease suggests that the inflammation is due directly to disease activity, possibly to immune complex deposition in small vessels.[15] It is interesting that two of three patients in one series had syndromes similar to viral hepatitis prior to the attacks of myocarditis; however, no specific viruses were identified.[15] The possibility of viral myocarditis, therefore, needs to be considered. It is well known that viral illness may induce a flare-up of systemic disease in JRA patients. It is therefore possible that a viral illness may trigger the systemic features of JRA, including an inflammation of the myocardium. In another series of eight patients,[10] none had syndromes similar to viral hepatitis prior to the attacks of myocarditis, supporting the notion that myocarditis may be a feature of systemic inflammation secondary to the JRA itself.

Treatment of Myocarditis. The most effective treatment of myocarditis in JRA appears to be the use of high doses of corticosteroids. The avoidance of digoxin is recommended because the incidence of glycoside toxicity is high in these patients.[10,15] Clinical response to steroid therapy is usually dramatic, occurring within 24 to 48 hours. As steroids may be contraindicated in some forms of viral myocarditis, a careful clinical evaluation is necessary before starting treatment.[15] The signs of some viral infections that can cause myocarditis may mimic JRA, but differences in the rash, fever curve, joint disease, and systemic symptoms may help to distinguish these from JRA.

Valvular Involvement

Valvular heart disease is rare in patients with JRA. When present, valvular complications usually affect the aortic valve. Severe aortic insufficiency has been described in patients with all three onset types of JRA. Leak et al. described four patients with seropositive JRA and severe aortic incompetence.[18] Three of these four patients had subcutaneous nodules. Seropositive JRA resembles adult rheumatoid arthritis, and when valvular lesions occur in the adult patient, the aortic valve is the one most commonly affected. The valvular incompetence in this series of patients progressed in a short period of time. In cases with rapid progression to severe aortic regurgitation, aggressive surgical management may be necessary. The histology of the valves of two patients studied revealed destruction of the normal architecture by rheumatoid granulation tissue. In at least one case active nodular lesions were responsible for the destruction of the valve. Kramer et al. described severe aortic insufficiency in a patient with systemic onset JRA.[19] Histology of the valve of this patient revealed nonspecific changes with necrosis and fibrosis. Hull et al. described a patient with seronegative, HLA-B27–negative, pauciarticular-onset JRA with aortic incompetence, presumably due to aortitis.[20] Thus, both specific granulomatous nodules and nonspecific lesions have been found in the hearts of patients with JRA. Many of these patients eventually required valve replacement. Hull et al. reported clinical improvement with the use of chlorambucil, an immunosuppressive agent[20]; however, more cases need to be studied before one can safely assume a nonsurgical approach to the treatment of severe valvular disease. Criteria for aortic valve replacement in aortic regurgitation from rheumatoid arthritis are the same as those for congenital or rheumatic heart disease. Careful examination to identify even minor valvular abnormalities is important in the patient with JRA because of the need in these children for bacterial endocarditis prophylaxis.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a multisystem disease characterized by widespread inflammation and marked and varied immunologic abnormalities, including a variety of autoantibodies that participate in immunologically mediated tissue injury. Any organ system may be involved; multisystem involvement is common. In 1982, a revised set of criteria for the diagnosis and classification of SLE were established[21] (Table 88–1). The *malar rash* is described as a fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds. The *discoid rash* is described as erythematous raised patches with adherent keratotic scaling and follicular plugging. Atrophic scarring may occur in

Table 88–1. Revised Criteria for the Diagnosis and Classification of SLE*

Malar rash
Discoid rash
Photosensitivity
Oral or nasopharyngeal ulcerations
Arthritis
Serositis
Renal disorder
Neurologic disorder
Hematologic disorder
Immunologic disorder
Antinuclear antibody

*Four or more of the criteria should be present for a diagnosis of SLE.

older lesions. *Photosensitivity* may present as a skin rash as a result of an unusual reaction to sunlight. The *oral* or *nasopharyngeal ulcerations* are usually painless. The ulcerations are most common on the hard or soft palate. These ulcerations are usually not symptomatic and are likely to be noted only if looked for. The *arthritis* is characterized as nonerosive arthritis characterized by tenderness, swelling, or effusion. Joint involvement is a common manifestation of SLE and may precede the onset of multisystem disease by months to years. Deforming arthritis may occur but is unusual. *Serositis* includes pleuritis and pericarditis. Pleuritis is defined as a convincing history of pleuritic pain, a rub heard by a physician, or radiographic evidence of pleural effusion. Pericarditis is documented by ECG, by a friction rub, or by echocardiographic evidence of pericardial effusion. The clinical criteria for *renal involvement* include persistent proteinuria greater than 0.5 g per day (or greater than 3+ if quantitation is not performed) or the presence of cellular casts on urine microscopy, including red cell, hemoglobin, granular, tubular, or mixed types. The incidence of renal involvement has been cited to be as high as 60 to 80%.[22,23] The extent of renal involvement may vary from isolated histologic abnormalities on immunofluorescent studies, to mild proteinuria or hematuria, to nephrotic syndrome or frank nephritis.

Four main morphologic types of lupus nephritis have been identified.[24]

1. Mesangial (minimal) lupus nephritis, characterized by glomeruli that appear normal or merely show a slight irregular increase in mesangial cells and matrix. Immunofluorescent staining demonstrates IgG and C3 in the mesangium.
2. Focal (mild) lupus nephritis, characterized by segmental proliferation of some glomerular tufts while others appear normal.
3. Diffuse (severe) proliferative lupus nephritis, characterized by abnormalities of more than 50% of the total area of the glomerular tufts. Although the proliferation is irregular, all glomeruli are involved and usually most of each glomerulus is abnormal.
4. Membranous lupus nephritis, histologically similar to idiopathic membranous glomerulonephritis.

Neurologic disorders include seizures (in the absence of offending drugs or known metabolic derangements) and psychosis (also in the absence of offending drugs or known metabolic derangements). *Hematologic disorders* include hemolytic anemia with reticulocytosis, leukopenia less than 4000/μL on two or more occasions, lymphopenia less than 1500/μL on two or more occasions, thrombocytopenia less than 100,000/μL in the absence of offending drugs. These abnormalities are thought to be mediated by autoantibodies directed against the particular cell type. To fulfill the criteria for an *immunologic disorder* one must demonstrate a positive LE cell preparation, antibodies directed against native DNA, antibodies directed against Sm nuclear antigen, or a false-positive serologic test for syphilis confirmed by Treponema pallidum immobilization or fluorescent treponemal antibody absorption test. *Antinuclear antibodies* are the final criteria and should be considered only in the absence of drugs known to be associated with "drug-induced lupus syndrome."

Four or more of the criteria listed in Table 88–1 and described above should be present for the diagnosis of SLE. Other manifestations of the disease may include fatigue, fever, weight loss, alopecia, Raynaud's phenomenon, myositis, myalgia, rheumatoid nodules, tenosynovitis, thrombophlebitis, abdominal pain, pancreatitis, hepatosplenomegaly, lymphadenopathy, conjunctivitis and/or episcleritis, peripheral neuropathies, pneumonitis, and the cardiac manifestations (described below).[25] The systems most commonly involved in children are the joints, skin, kidneys, and pleuropericardial surfaces.[22,23]

Laboratory evaluation in SLE generally reflects the presence of autoantibodies and immune complex disease. Hematologic parameters may reflect the presence of anti–red blood cell, antiplatelet, anti–white blood cell, or antilymphocyte antibodies, as mentioned above. Antinuclear antibodies are directed against nuclear constituents and are the most characteristic autoantibodies of SLE.[26] Several patterns of immunofluorescence have been described. Antibodies to native or double-stranded DNA are fairly specific for SLE.[27] Evaluation of antibodies to extractable nuclear antigens (anti-ENA antibodies) may be useful and include anti-Sm and antiribonucleoprotein (anti-RNP) antibodies. Complement determinations often reflect the presence of ongoing immune complex disease with low C3, C4, and hemolytic complement results. The determination of circulating immune complexes (Raji cell assay or C_{1q} binding assay, for example) will usually reveal positive results. Urinalysis may reveal microscopic hematuria, proteinuria, or both. Coombs' antibodies may be present. Some patients with lupus have a circulating antibody (IgG, IgM, or both) that prolongs phospholipid-dependent coagulation tests by binding to portions of the phospholipid moiety of prothrombinase (a complex factor Xa, factor Va, phospholipid, and calcium).[28] This antiphospholipid antibody is termed the *lupus anticoagulant*. The hallmark of the lupus anticoagulant is prolongation of phospholipid-dependent coagulation tests (PT, APTT, and clotting time) without correction by admixture with normal plasma.[29] There is a strong correlation between the presence of the lupus anticoagulant and elevated titers of antibody to cardiolipin; the presence of either or both is associated with a high incidence of thrombosis.[30] Thus, the name lupus anticoagulant is really a misnomer as it has become clear that it is more frequently encountered in patients without lupus and it is not generally associated with abnormal bleeding except when hypoprothrombinemia, thrombocytopenia, or a qualitative platelet defect is present.

Cardiovascular Manifestations of SLE

Cardiovascular abnormalities have been reported in 50 to 80% patients with SLE.[31] The involvement may range from a nondiagnostic murmur and ECG changes to pericarditis, myocarditis, Libman-Sacks endocarditis, arrhythmias, coronary arteritis, and complications of systemic and pulmonary hypertension. With the increase in survival, seen since steroids were introduced in the late 1940s, and with advancement of diagnostic modalities, cardiovascular manifestations of SLE have become more apparent.

Pericarditis

Pericarditis is the most frequent cardiac manifestation of SLE, occurring in up to 30% of children with acute systemic disease.

Clinical Presentation of Pericarditis. Pericarditis may be clinically represented by recurrent painless effusions or by classical precordial pain exacerbated by certain physical positions or by deep breathing. A pericardial friction rub is sometimes heard, but does not necessarily correlate with the symptoms of pericarditis.[32] Evidence of pericarditis has been found at autopsy in over 62%

of lupus patients, but only 25% of these cases had clinically manifest pericarditis.[32] Although massive pericardial effusions may occur in SLE, pericardial tamponade is unusual, occurring in fewer than 1% of patients in a large series.[33] When present, it may be more frequent in drug-induced diseases[34,35] (see the section on drug-induced lupus). Constrictive pericarditis has been described in teenage patients with lupus.[36] Purulent pericarditis is rare and is usually seen in the context of a patient receiving corticosteroid therapy. When present, these cases are usually secondary to Staphylococcus aureus infection; however, tuberculosis has also been reported.[33]

The ECG may be helpful in confirming the presence of pericarditis, and usually reveals nonspecific ST-T wave changes.[37] The abnormalities may improve as the disease is treated. The echocardiogram is the most sensitive method of confirming the presence of pericardial fluid. Pericardial thickening may be more common than pericardial effusion in patients with SLE.[38,39] When pericardiocentesis is performed, the pericardial fluid is generally an exudate that may be clear to hemorrhagic, with normal glucose; numerous leukocytes; predominantly polymorphonuclear cells; and evidence of an immunologically mediated process with the presence of LE cells, antinuclear antibodies, anti-DNA antibodies, rheumatoid factor, immune complexes, and cryoglobulins.[32,33,40,41] The pericardial fluid complement in lupus patients is also lower than predicted values (pericardial fluid complement is usually one third that in serum); however, this is not specific for lupus.[41] Pathologically, the pericardium may be affected diffusely or focally.[33] In chronic cases the pericardial space may be obliterated by fibrous adhesions. In more acute cases, fibrous exudates may be found. The fact that pericardial involvement has frequently been detected in autopsy studies in patients who had neither signs nor symptoms of pericarditis may indicate that much of the pericardial involvement in SLE is asymptomatic and subclinical.[32,37]

Treatment of Pericarditis. The management of pericarditis in SLE depends upon the severity of involvement.[32,33,41] Asymptomatic, hemodynamically insignificant pericardial effusions do not generally require treatment. NSAIDs are often effective in symptomatic cases. More serious cases may require corticosteroid therapy. Steroids are usually effective in resolving the symptoms and diminishing the pericardial fluid within a few days, without the necessity of pericardiocentesis. Absence of any response to corticosteroids should warn of the possibility of infectious pericarditis even in a patient with an established diagnosis of lupus.[42] Pericardial tamponade may require pericardiocentesis; however, there is no clear cut role for intrapericardial steroid administration.

Myocarditis

Myocarditis involvement in SLE is much less common than is pericarditis.

Clinical Presentation of Myocarditis. Clinical manifestations of myocarditis include tachycardia, an enlarging heart, CHF, arrhythmias, and conduction defects. The clinical diagnosis of lupus myocarditis was made in 8% of 520 cases of lupus described by Dubois; the diagnosis was based on the presence of tachycardia out of proportion to fever, cardiomegaly, or a gallop rhythm.[43] Many of these patients had concomitant pericarditis. Bulkley and Roberts described myocardial inflammation in only eight of 36 autopsy patients.[44] Strauer et al. demonstrated that lupus cardiomyopathy may affect the intrinsic contractile properties of the myocardium and may exist even in young patients without clinical signs of cardiac dysfunction.[45] They studied five patients with SLE who had no clinical signs of cardiac dysfunction except for a soft and uncharacteristic systolic murmur. Electrocardiogram and chest radiographs demonstrated no arrhythmias, conduction defects, cardiac hypertrophy, or cardiomegaly. They found abnormalities of myocardial contractility and coronary hemodynamics in all five patients, including 1) increases in right and left ventricular end-diastolic pressures; 2) decreases of indices of cardiac contractility; 3) increases of end-systolic volume and decreases of the ejection fraction of the left ventricle; 4) increases of left ventricular wall stiffness as indicated by increases of dP/dV; and 5) normal coronary blood flow under resting conditions, although there was a marked reduction of coronary vascular reserve. Whether there is a cardiomyopathy directly attributable to lupus is uncertain. Other factors contributing to CHF in patients with SLE must be considered, including fever, infection, anemia, uremia, hypertension, steroid use, and accelerated atherosclerosis.[33] There is some evidence that immune dysfunction in lupus may contribute to the pathogenesis of the cardiomyopathy. Borenstein et al. reported that lupus myocarditis is frequently associated with generalized skeletal muscle myositis.[46] The patients in that study also demonstrated circulating antibodies to nuclear RNP in high titer. These findings suggest a possibility of a common pathogenetic mechanism for cardiac and skeletal muscle inflammation in SLE and lend support to a possible association of anti-RNP antibodies with inflammatory muscle disease in these patients. Das and Cassidy described anti-heart antibodies in 20 of 32 patients with SLE.[47] Antibodies were present with equal frequency in patients with and without clinical cardiac disease. The authors postulated that these antibodies represented an immunologic response to release into the circulation of altered myocardial antigen. Bidani et al. found evidence of immune complex deposition in nine of 10 necropsies and proposed that immune complex deposition may lead to complement activation, inflammation, and myocardial damage.[48] Either mechanism—anti-heart antibodies or immune complex deposition—may cause small vessel vasculitis, focal myocarditis, febrosis, and myocardial necrosis.[33]

Treatment of Myocarditis. Digitalis glycosides and diuretics are indicated when lupus patients develop cardiac insufficiency. If lupus myocarditis is suspected, corticosteroid therapy should be considered.[32]

Myocardial Infarction and Coronary Artery Disease

Acute myocardial infarction (MI) has been reported early in the course of disease in young SLE patients, including some patients who had not previously received steroids.[49–56] A number of causes have been proposed, including coronary arteritis,[32,33,44,54] thrombosis,[50,51] accelerated coronary artery atherosclerosis,[44,49,53,55] and coronary artery spasm.[52] The thrombosis, when present, is often associated with anticardiolipin antibodies and the lupus anticoagulant (discussed earlier). The accelerated coronary artery atherosclerosis is thought to be secondary to an immune response in the arteries and/or the effects of corticosteroid therapy. It is well known that corticosteroid therapy may induce a variety of coronary risk factors, including hypertension, hyperlipidemia, and diabetes mellitus. Attempts to minimize the corticosteroid dosage in lupus patients should be stressed. It is conceivable that alternate-day regimens may decrease the risk of coronary artery disease. This

assumption is reasonable since the diabetes mellitus and hypertension that can be induced by daily steroid administration to children with SLE decrease on alternate-day regimens.[31] Normalization of blood pressure and perhaps cholesterol levels may be important in preventing coronary artery disease in patients with SLE.[32]

Endocarditis

Libman and Sacks are credited with the early descriptions of verrucous vegetations found on the valves of lupus patients.[57] These vegetative lesions, found at autopsy, were the original pathognomonic diagnostic criteria of SLE. The verrucae may appear as pea-sized, flat or slightly raised, granular gray or pinkish projections, densely adherent to the endocardium. They occur most frequently at valve rings and commissures, and spread over both valve surfaces, valve pockets, and even onto atrial and ventricular mural endocardium, chordae tendineae, and papillary muscles. Microscopically, the vegetations consist of proliferating and degenerating cells, fibrin, fibrous tissue, and occasional hematoxylin bodies. There may be variable amounts of inflammation with a mild scattering of plasma cells and large mononuclear cells.[33] The diagnosis of Libman-Sacks endocarditis is primarily made at autopsy. Bulkley and Roberts found evidence of endocarditis in 50% of autopsied patients.[44] The mitral valve is most commonly involved, especially the recess between the posterior mitral valve leaflet and ventricular wall. Only unusually large verrucous lesions may be visualized clearly on echocardiograms.[33] The incidence of Libman-Sacks endocarditis has declined in the past 30 years, possibly secondary to steroid therapy. Most authors believe that lupus endocarditis is usually clinically insignificant. The lesions are rarely reported to cause valvular dysfunction and consequently the diagnosis of Libman-Sacks endocarditis has been established almost exclusively at necropsy.[58] Peripheral embolization, infective endocarditis, and severe valvular insufficiency have been reported, but are uncommon.[32]

Hemodynamically, significant regurgitant lesions may affect the aortic or mitral valve in SLE.[33,58] Aortic insufficiency is the most common serious problem and may be due to multiple causes in addition to verrucous endocarditis, including valvulitis, fibrosis, mucoid degeneration and fenestrations, bacterial endocarditis, and aortic dissection.[33] Hemodynamically significant mitral regurgitation is less common and has been attributed to thickening and calcification of the mitral valve leaflets, chordae tendineae scarring, fibrosis, fibrinoid necrosis of papillary muscles, and rupture of chordae tendineae.[33]

Conduction Abnormalities

High grade AV block and life-threatening arrhythmias have been reported in young patients with SLE but are uncommon.[59–61] The causes of these lesions include vasculitis of the arteries near the sinus and AV nodes and bundle of His and extension of the inflammatory lesions of myocarditis to involve the cardiac conduction system. There are many similarities to the pathologic findings seen in neonatal lupus erythematosus (see the section on neonatal lupus erythematosus).

Pulmonary Hypertension

Pulmonary hypertension has been reported to be a major clinical manifestation in some patients with SLE.[62–64] One study suggested that development of pulmonary hypertension during the course of SLE is usually associated with a significant degree of pulmonary parenchymal involvement.[62] In some patients in this study, however, the degree of pulmonary hypertension observed was disproportionate to the degree of parenchymal involvement present, suggesting a pathogenetic mechanism involving the pulmonary arteries. The clinical response to vasodilator and corticosteroid therapy is not always favorable.[62,63]

DRUG-INDUCED SYSTEMIC LUPUS ERYTHEMATOSUS

It is well recognized that SLE may occur after the ingestion of certain drugs. The clinical criteria for the diagnosis of drug-induced lupus are the same as those for the diagnosis of SLE.[21] The following are additional requirements.[65]

1. A drug must have been administered before the onset of any sign or symptom used as one of the criteria for the SLE diagnosis.
2. The disease process must reverse itself promptly upon cessation of drug treatment. Clinical signs and symptoms must begin to clear within days; serologic findings may persist for months. Patients who develop lupus while receiving anticonvulsants may not always enter complete and permanent remission after the cessation of the drug. In the few cases where it has been tried, resuming the drug therapy seems to result in prompt recrudescence of the symptoms. One must question whether the convulsive disorder may actually have been the first evidence of spontaneous SLE.

The course of drug-induced SLE depends on how long the drug is administered after the symptoms first appear.[65] In general, symptoms increase in variety and severity with continuation of the inducing agent. In general, the clinical picture of drug-induced SLE differs little from that of the spontaneously occurring disease. Patients with drug-induced lupus may have a lower incidence of nephritis and a higher incidence of pleural and pulmonary involvement than that reported in spontaneous SLE.[66] It also appears that pericardial tamponade is more frequent in the drug-induced disease than in spontaneous disease.[34,35] One must differentiate between the induction of antinuclear antibodies in the asymptomatic patient and true drug-induced SLE.

Classification of Lupus-Activating Drugs

The more than 40 drugs now associated with SLE have been categorized according to the strength of conviction about their ability to cause symptoms that conform to the standard diagnostic criteria[67] (Table 88–2). The ''definite'' category includes drugs with proven ability to cause SLE, not simply to cause a positive antinuclear antibody (ANA) test with no, or only a few, lupus symptoms, to exacerbate existing SLE, or to be mistaken for the cause of pre-existing SLE. This category includes only three drugs: procainamide, hydralazine, and isoniazid. The ''possible'' and ''unlikely'' categories include drugs that have been sporadically associated with SLE but have not been confirmed in prospective studies to have a causal rather than a correlational relationship. These drugs may well produce an SLE-like syndrome, but there is simply not enough objective evidence to justify their inclusion in the ''definite'' category.

Procainamide may be the most potent drug in the group. Be-

Table 88–2. Drugs That May Induce Systemic Lupus Erythematosus*

Definite	*Possible*	*Unlikely (but Implicated)*
Hydralazine	Phenytoin	Methysergide
Procainamide	Mephenytoin	Gold salts
Isoniazid	Trimethadione	Allopurinol
	Primidone	Phenylbutazone
	Ethosuximide	Oral contraceptives
	Methyldopa	Reserpine
	Quinidine	Chlorthalidone
	Propylthiouracil	Tetracycline
	Methylthiouracil	Streptomycin
	Nitrofurantoin	Griseofulvin
	Lithium carbonate	Sulfonamides
	Penicillamine	Captopril
	Chlorpromazine (and other phenothiazines)	Cimetidine
		Practolol
		Atenolol

*Modified from references 67 to 77.

tween 15 and 100% of patients taking this drug will develop ANAs within one year, and 5 to 30% will develop drug-induced SLE.[67] Symptoms in most cases develop only after continuous administration of drug for 3 months to 2 years.[65] Hydralazine is the next most potent drug, inducing antinuclear antibodies in 24 to 50% of patients and symptoms of drug-induced SLE in 8 to 13% of cases.[67] For both of these drugs, the larger the daily dose or total dose, the more likely will be the development of drug-induced SLE. In an adult, 400 mg per day or more of hydralazine or 1.25 mg per day of procainamide is associated with an increased frequency of positive ANAs and/or lupus symptoms.[67]

Hydralazine is metabolized largely by acetylation in the liver. A genetically controlled polymorphism exists in the hepatic acetyltransferase responsible for detoxification. Individuals are classified as either slow or fast acetylators. Slow acetylators are more likely to develop positive ANAs and lupus-like symptoms.[65] Isoniazid is also acetylated by the liver, and slow acetylators are more likely to develop drug-induced lupus. Procainamide is metabolized similarly. Thus, at least for these drugs, patients in whose circulation undetoxified drug remains longer are at higher risk for developing disease.

Methyldopa has not been placed on the list of definite drugs implicated in drug-induced lupus. While it has been reported to cause SLE in a few patients, it appears to induce antinuclear antibodies in a significant number of asymptomatic patients. It more frequently causes a positive Coombs' test and hemolytic anemia.[66]

Diagnosis of Drug-Induced Lupus

Antinuclear antibodies are found in every patient with drug-induced lupus. The titer does not have diagnostic importance. The pattern is usually homogeneous or speckled. The antibodies are directed largely against histones, which accounts for the homogeneous pattern. The histones are distributed in the nucleus in a "speckled" pattern.[67] Although antihistone antibodies are strongly associated with drug-induced disease, they are also frequently seen in patients with spontaneous SLE.

The diagnosis of drug-induced lupus depends on the recognition of the ingestion of a drug known to induce the disease. Symptoms of the disease should abate quickly after discontinuation of the medication. The diagnosis of SLE secondary to anticonvulsant drugs is difficult. Seizures are a well-recognized manifestation of SLE; thus, it must be questioned whether the child who develops seizures and is treated with an anticonvulsant drug and later manifests signs of SLE has spontaneous or drug-induced SLE.

Although there have been no reports of infants with congenital complete AV block born of mothers with drug-induced SLE (this form of SLE is associated with an anti-histone rather than La or Ro), consideration should be given to discontinuing the offending therapy during pregnancy, if possible.

Management of Drug-Induced Lupus

Once a drug is suspected of causing drug-induced lupus, attempts to discontinue its administration should be made. If the clinical manifestations do not disappear promptly or are disabling, NSAIDs may be given. Corticosteroids are sometimes necessary for the pleuropericardial symptoms. The continued presence of antinuclear antibodies in the serum after the clinical manifestations of disease have disappeared should be expected; treatment should not be given for the presence or persistence of ANAs in the absence of clinical disease. If a patient has ANAs but no symptoms, the drug does not need to be withdrawn, since SLE does not develop in the majority of these patients.

The use of these potential disease-inducing drugs is not necessarily contraindicated in the treatment of patients with spontaneous SLE. One needs to consider the risk–benefit ratio and spectrum of therapeutic choices available. If these drugs are to be used in patients with SLE, one must watch closely for the exacerbation of the disease.

NEONATAL LUPUS ERYTHEMATOSUS

Neonatal lupus erythematosus (NLE) is a disease of infants characterized by congenital AV block and/or transient cutaneous lesions, often associated with hepatic or hematologic abnormalities. McCuiston and Schoch[78] are credited with the first report of NLE. Many of the early descriptions involved children of mothers with overt connective tissue disease, but it is now recognized that many mothers are asymptomatic or have mild symptoms of sicca syndrome or other connective tissue diseases.

Clinical Presentation of NLE

Lupus manifestations in the neonate can be divided into five categories.[79] (The numbers in parentheses represent approximate relative frequencies of the affected population.[80])

1. Infants with transplacental passage of antibodies, resulting in serologic markers of lupus such as LE cells, antinuclear antibodies and even occasionally low serum complement without symptoms. The exact frequency of these findings is unknown since they have not been systematically studied.
2. Infants with Coombs'-positive hemolytic anemia, thrombocytopenia, and/or leukopenia with or without skin lesions (15%).
3. Infants with skin lesions without other manifestations (26%).
4. Infants with skin lesions and other symptoms, including heart disease (15%).
5. Infants with congenital complete AV block without other signs of SLE (44%). It is emphasized that infants in this group, if their mothers are seropositive, have NLE.

Dermatologic Manifestations of NLE

Skin lesions in NLE may be present at birth, but usually develop within the first 3 months of life and usually resolve by 6 to 12 months.[81–83] There is a predilection for sun-exposed areas, especially the face, scalp, and neck, and initial lesions may suggest seborrheic dermatitis or tinea corporis. Individual lesions may rapidly develop into disk- or geographic-shaped erythematous macules, papules, or plaques, with a distinct margin separating normal skin from the lesions. Follicular plugging, hypo- or hyperpigmentation, telangiectasia, atrophy, and scarring may occur but are not usual features. The lesions may resemble the discoid lesions seen in older children and adults with SLE. Biopsy specimens of active skin lesions show the pathologic features of lupus, which include plugging of the hair follicles, focal liquification and degeneration of the basal cell layer of the epidermis, edema, and a patchy mononuclear cell infiltrate in the dermis.[82] Immunofluorescent staining of skin lesions may be positive for complement, IgM, or IgG at the dermo–epidermal junction.[82] A majority of lesions become polycyclic and appear to be identical to the lesions initially described by Sontheimer et al. in the syndrome of "subacute cutaneous lupus erythematosus."[84]

Hematologic Manifestations of NLE

Transient Coombs'-positive hemolytic anemia, thrombocytopenia, and/or leukopenia have been described in infants with NLE.[80,85] These manifestations are most likely secondary to transplacental passage of maternal IgG antibodies directed against red blood cells, platelets, and/or white blood cells.[86,87]

Cardiac Manifestations of NLE

Congenital AV block is the most serious complication of NLE and has been described in more than 100 infants with the disease.[80–82,85,88–89] Most of the cases of congenital AV block were diagnosed near the time of birth. In one study, 36 of 38 cases of AV block were diagnosed within three months before or after birth.[93] The AV block ranged from partial to complete. The location of the block is thought to be in the region of the atrioventricular node, as evidenced by narrow QRS pattern and a ventricular rate that varied between 45 to 60 beats per minute.[92] A cardiomyopathy has also been recognized in a number of these infants.[92,99,100] Postmortem studies of hearts of infants with isolated congenital AV block have revealed fibrosis and calcification along the ventricular portions of the conduction system.[88,92] A discrete atrioventricular node and/or bundle of His are often unrecognizable, replaced by elastic, fibrous, or adipose tissue and by venous channels.[88,92,93] The pathologic findings are not restricted to the conduction system. Autopsies in a few patients have revealed extensive myocardial fibrosis,[88,89,92] and in at least one reported case, fibrosis of the liver, spleen, kidneys, and adrenals.[88] Both Litsey et al.[98] and Taylor et al.[99] demonstrated antibody deposition in atrial tissue, providing strong evidence that antibodies transmitted placentally may act directly on cardiac tissue to produce complete AV block.

Systemic Manifestations of NLE

Transient elevation of liver function tests,[83,85] which may be associated with hepatomegaly, pneumonitis,[83] and urinary tract abnormalities,[85] have been described.

Sex Incidence

Previous reports suggested a preponderance of females among NLE infants with cutaneous disease (female:male ratio, 9:1)[81] and less so among those with congenital AV block alone (female:male ratio, 1.6:1).[80] Watson et al.[83] have suggested that with the addition of several more cases, susceptibility between the sexes is equal, suggesting that the clinical expression in NLE is not sex hormone–dependent.

Serologic Abnormalities

The Ro antibody system was first reported by Clark et al. in 1969.[101] The Ro title was taken from the surname of a patient who had a syndrome clinically consistent with SLE but who had a negative antinuclear titer. This patient's serum showed a unique precipitin antibody that reacted against a cytoplasmic extract of human spleen, later found to be a soluble tissue ribonucleoprotein. Later, Alspaugh and Tan[102] showed that patients with Sjögren's syndrome possess antibodies to a nuclear antigen SSA. Further studies revealed that the Ro and SSA systems were immunologically identical.[103] A related antigen—La—was found similarly to be identical to SSB. It is of great importance that most of the mothers of infants with neonatal lupus possess antibodies to this Ro/SSA antigen regardless of whether the mother was symptomatic with a connective tissue disease.[81–83,93,94,98] This antibody is found in most infants with NLE in the neonatal period, but is absent after 6 months of age, suggesting maternal transplacental transfer of this IgG antibody. It has been suggested that maternal antibody to Ro might serve as a marker to identify women at risk of having an infant with congenital AV block.[92] Circulating anti-Ro antibodies alone are not sufficient to cause the disease, as not all mothers who are Ro antibody–positive will give birth to affected infants. Some studies suggest that 5% or fewer of the infants exposed to maternal Ro antibody subsequently have features of neonatal lupus.[83] Routine fluorescent ANA testing of mothers is not sufficient, as the Ro antibody is not detected when mouse or rat tissue is used as the substrate of ANA testing. One must use human tissue as the substrate and this is not routinely used for ANA testing. The frequency of the La (SSB) antibody in NLE infant/mother pairs is also noteworthy.[83] Provost et al. recently

reported two cases of NLE characterized by the absence of anti-Ro or anti-La antibodies but the presence of anti-U_1 RNP antibodies, in the infants and their mothers.[104]

HLA Studies

In NLE, a disease in the mother characterized by autoantibody production results in clinical expression involving several organ systems in her infant. This has prompted a number of studies investigating the genetic influences on autoantibody production and clinical expression of a disease. Lee et al. have examined the HLA phenotype of six families with infants with NLE.[81] They found a significant association with HLA-DR3 in the mothers, but not in the affected infants. Lockshin et al. found similar results,[95] while Lumpkin et al. found that two of three infants and mothers studied carried the DR3 phenotype.[105] Of further interest was the increased frequency of HLA-B8, -MB2, and -MT2 phenotypes in NLE mothers.[81,83] These antigens are known to be in linkage disequilibrium, or to cross-react, with HLA-DR3. No association was found between these HLA antigens and expression of disease in infants. The finding of an association with HLA-DR3 and other linkage HLA antigens in mothers, but not in infants, supports the concept that autoantibody production is related to genetically determined products of the major histocompatibility complex. Watson et al. hypothesized that the presence of certain HLA phenotypes (notably DR2) may protect against complete clinical expression of this disease in the neonate.[83]

Risk of Development of NLE in Siblings

Despite the consistency of disease symptomatology and/or serology in the mother, the expression of disease can vary in the infants involved. Both Scott et al.[93] and Callen et al.[106] described dizygous twins with discordant disease expression of NLE; one twin had NLE, and the other was apparently unaffected. A review of the literature by Lanham et al. revealed that eight of 42 (19%) of siblings of 32 NLE probands had congenital AV block.[96] In a recent study, 25% of subsequent live births had NLE.[97] Disease expression in siblings may also vary in severity.[88] It appears that the rate of miscarriages or still births may be increased in these mothers.[93]

Etiology

It is unclear whether the atrioventricular node in NLE infants with congenital AV block is destroyed, fails to develop appropriately, or is prevented from joining the bundle of His by connective tissue interference. Evidence from postmortem studies raises the possibility of at least two hypotheses to explain the congenital AV block in these infants.

First, it is known that the atrioventricular node originates in the third to fourth week of gestation separately from the bundle of His and subsequently joins it. An injury may occur early in gestation during a critical period of organogenesis, with the embryonic nodal anlage failing to form a compact atrioventricular node and establish normal relations to the interatrial septum and annulus. The inability to find a discrete atrioventricular node and/or bundle of His may support this theory.[88,92,93] IgG antibodies can cross the placenta as early as 12 weeks of gestation and could potentially interfere with cardiac embryogenesis. Neither IgA nor IgM can cross the placenta, and their presence in fetal tissues would suggest fetal production of these antibodies. The finding of IgA[98] and IgM[99] deposition raises the additional possibility that cardiac tissue damaged by maternal antibody or an as yet unknown substance may be rendered immunogenic in the fetus, with the subsequent production of IgA and IgM antibodies.

Second, a definitive atrioventricular node develops during cardiac organogenesis but is subsequently destroyed and fibrosed. An active inflammatory process occurring in the fetal atrioventricular junctional tissues could result in destruction and fibrosis of these vital areas. A number of issues support this theory.

1. The majority of maternal antibodies cross the placenta in the third trimester, thus appearing too late to interfere with embryogenesis; however, sufficient antibody is present to participate in immune-mediated inflammation.
2. When the atrioventricular node is found, it is often in a sea of dense connective tissue.[83]
3. AV block, although rare in the adult with SLE, has been described and the pathological changes associated with it are identical to those of NLE.[59–61]
4. Normal heart rate and function have been documented earlier in the pregnancy prior to the development of complete AV block.[100]
5. ECG patterns in some infants with complete AV block have demonstrated abnormal rhythms elsewhere in the heart, usually early in life, and in particular atrial flutter and premature contractions.[107]

Ro/SSA antigen has been shown to be present in the skin, heart, and other internal organs.[108] It is conceivable that anti-Ro antibodies, or another unidentified antibody system, might induce an inflammatory response preferentially affecting the richly vascular parts of the heart, including the conduction system.[83] In a study investigating the association between congenital AV block and maternal antibodies capable of crossing the placenta, Taylor et al.[99] reported that serum antibodies reactive with fetal heart tissue were present in a significantly higher proportion in mothers of infants with congenital complete AV block than in controls. These antibodies consisted predominantly of IgG and therefore were able to cross the placenta. In addition, these antibodies did not react selectively with the conduction system, but reacted with other all myocardial tissue, as well as with other fetal tissues.

One must question why the mothers of these infants are not similarly affected. These mothers almost always have serum antibodies to Ro (SSA) and to La (SSB), but the reverse is not true, suggesting additional factors are necessary to induce the pathologic conditions.[99] The finding of Ro antibody in the serum of these mothers and infants may be an epiphenomenon. Other hypotheses include the possibility that the mothers have blocking antibodies of IgA or IgM class, thereby protecting their conduction system from immunologic assault. Or, it is possible that the developing conduction system is more sensitive to immune-mediated inflammation than the mature system.

Prognosis

The prognosis of NLE in the absence of congenital AV block is excellent: the clinical and serological features disappear by 1 year of age.[83] The presence of AV block increases the mortality.[83,109] In one study, infants who survived continued to have AV block, and some had severe cardiomyopathy or associated congenital defects.[110] There have been reports that some NLE infants later developed other connective tissue diseases, including

SLE,[96,110,111] juvenile rheumatoid arthritis,[91,107] or Sjögren's syndrome,[96] but this appears to be unusual.

Management of Mothers and Infants with NLE

Mothers suspected of having infants with NLE should be monitored closely during pregnancy for signs of fetal bradycardia or fetal distress. Buyon et al.[100] reported the successful treatment with dexamethasone and plasmapheresis in a mother whose fetus abruptly developed AV block and myocarditis. At birth, there was no evidence of myocarditis, although there was evidence of AV block. Herreman and Galezowski, however, reported less successful results with steroid therapy and plasmapheresis, although therapy was not instituted until after 23 weeks when there was already evidence of fetal bradycardia.[112] Currently, there are no clear cut recommendations for treatment of these mothers during pregnancy. The asymptomatic mothers should be monitored for later development of connective tissue diseases, most notably SLE, rheumatoid arthritis, or Sjögren's syndrome. In a recent study, half the mothers were initially asymptomatic despite having anti-Ro antibodies. When followed for a mean of 4.5 years, 18 of 21 mothers developed symptoms of connective tissue disease.[97]

Infants with NLE should avoid unnecessary exposure to ultraviolet light, as this may exacerbate or trigger the cutaneous disease.[83] In most cases, no therapeutic intervention is necessary for the skin disease as most of the lesions will disappear spontaneously. Infants with complete AV block may require pacemakers. The AV block is virtually always permanent. The hematologic abnormalities usually resolve spontaneously as the maternal antibodies disappear, but may require transfusion therapy.

SPONDYLOARTHROPATHIES

The term *spondyloarthropathy* refers to a spectrum of seronegative arthritic diseases consisting of ankylosing spondylitis, juvenile ankylosing spondylitis, the spondylitis of inflammatory bowel disease, Reiter's disease and several other postinfectious arthropathies, and psoriatic arthritis. They are termed "seronegative" because the rheumatoid factor is consistently absent from the sera of affected patients. While patients with these diseases may demonstrate peripheral arthritis, the hallmark of these diseases is arthritis of the axial skeleton.

Ankylosing spondylitis is perhaps the best described spondyloarthropathy.[113] The disease is characterized by pain, stiffness, and loss of mobility of the back. The distribution of the pathologic changes in ankylosing spondylitis follows a characteristic pattern. The primary site of this inflammatory disease is the insertion of ligaments and capsules into the bone, or the enthesis; hence the term enthesopathy. The major target appears to be the joints of the axial skeleton, including 1) the nonsynovial (cartilaginous) synchondroses of the intervertebral spaces; 2) the diarthrodial synovial joints (apophyseal and costovertebral articulations); and 3) the sacroiliac joints, which possess features of both nonsynovial and diarthrodial articulations. Inflammation of the peripheral joints also occurs, with the hip, knees, and shoulders primarily involved. The major target tissue of inflammation is cartilage, especially fibrocartilage. There is often an associated osteitis of the directly adjacent subchondral bone. In 80% of patients, initial complaints are usually referable to the sacroiliac joints and low back and consist of pain and stiffness in the low back, buttocks, thighs, and hips.[114] These symptoms are often transient and recurrent for years before obvious loss of spinal mobility occurs. In about 20% of patients, the disease begins with arthritis of peripheral joints, and in about half the patients peripheral joints are affected at some time during the course of the disease.[114] Diagnosis is based on the clinical picture and the presence of characteristic radiographic changes of the sacroiliac joints.[115] Ankylosing spondylitis is usually considered to be a disease that affects young adult males. It had been recognized for years that ankylosing spondylitis often occurs in families. The search for the explanation of this increased family prevalence took a dramatic step forward in 1973 when two reports defined the association of the genetic marker, HLA-B27, with ankylosing spondylitis.[116,117] HLA-B27 is found in approximately 90% of Caucasian patients with ankylosing spondylitis, as opposed to 8% of the general Caucasian population.

Ankylosing spondylitis has been described with a childhood onset.[114,118,119] In childhood it may be present with axial symptoms, similar to its presentation in adults. Or it may begin in childhood with peripheral arthritis, often misdiagnosed as pauciarticular juvenile rheumatoid arthritis. It may take several years before sacroiliac and spinal involvement becomes apparent. It is commonly believed that children in whom ankylosing spondylitis subsequently develops are usually boys, with pauciarticular or lower limb arthropathy (especially hip or hip girdle), whose disease onset occurs in late childhood, usually older than 8 years of age. These children are usually negative for rheumatoid factor or ANAs. However, as is true of adults, the vast majority are positive for HLA-B27.[120] The diagnosis is often delayed because of the rate of appearance of characteristic radiographic changes.[121] Both adults and children with ankylosing spondylitis may develop acute iritis.

In patients with ulcerative colitis and Crohn's disease, the rate of ankylosing spondylitis is higher than in the general population.[122–124] This spondylitis is different than the peripheral arthritis seen in patients with inflammatory bowel disease. This latter form of arthritis is usually associated with active disease, may be accompanied by erythema nodosum or pyoderma gangrenosum, and generally follows the course of the underlying disease, that is, when the colitis is cured, so is the acute arthritic problem. The spondylitis associated with inflammatory bowel disease is associated with the presence of HLA-B27 and follows its own course, often continuing after the colitis is eliminated.

A reactive arthropathy is an inflammatory arthritis in a patient who recently had an infection that did not involve microbial invasion of the joint space.[125] Again, most of the patients with reactive arthritis are HLA-B27 positive. The infectious agents most responsible include Shigella, Salmonella, Yersinia, and Campylobacter. These patients may present with fever, polyarticular arthropathy, and erythema nodosum. The symptoms may mimic those of acute rheumatic fever.

A classic form of postinfectious acute arthropathy is Reiter's syndrome.[125] Urethritis, conjunctivitis, and arthritis were once considered the classic triad. Buccal ulceration, balanitis, cervicitis, and keratoderma may also be part of the clinical picture. Rheumatologic features include arthralgia, tenosynovitis, plantar fasciitis, and other enthesopathies, as well as frank arthritis. Typically, the digits become sausage-shaped. HLA-B27 is present in 80% of patients with Reiter's syndrome and may follow dysenteric or venereal infections, especially Shigella and Chlamydia.

Cardiovascular Manifestations of the Spondyloarthropathies

Aortic Insufficiency

Like ankylosing spondylitis, acquired aortic regurgitation is predominantly a disease of adult males.[126] In children it is usually a sequela of acute rheumatic fever; less commonly it is the result of bacterial endocarditis or associated with Marfan's syndrome.

The association between aortic insufficiency and ankylosing spondylitis was originally described by Bauer et al.[127] The prevalence of aortic insufficiency increases with the duration of the spondylitis, occurring clinically in up to 10% of patients after 30 years and as high as 20% in postmortem studies.[127–131] In some patients, however, aortic regurgitation was present before distinctive radiologic changes of ankylosing spondylitis became apparent.[130]

Bulkley and Roberts[130] described the characteristic pathology of aortic regurgitation in ankylosing spondylitis. Their findings included cellular proliferation and scar formation resulting in a shortening and thickening of the aortic valve cusps, as well as a subaortic fibrous ridge or "bump." Scar tissue may extend into the subaortic area and infiltrate the membranous and muscular septum, producing mitral insufficiency and affecting the conduction system with resultant rhythm disturbance and AV block.[130,132–137]

Cardiac manifestations similar to those described in adults are relatively uncommon in juvenile ankylosing spondylitis.[126,138–141] Reid et al.[126] described a 9-year-old boy who developed restricted back mobility followed by severe peripheral arthritis. One year later, aortic insufficiency was detected. His cardiac lesion apparently was not progressive. Gore et al.[138] described a patient with the onset of peripheral arthritis at the age of 9 years, followed 2 years later by the development of aortic regurgitation and carditis. Six months later sacroiliac involvement was noted. One year later aortic insufficiency developed. Kean et al.[139] described a 15-year-old boy with severe polyarticular peripheral arthritis and uveitis who developed mild aortic regurgitation 1 year after the onset of arthritis. In 10 years of followup, the cardiac lesion had not progressed, peripheral arthritis had remitted, and sacroiliitis had not appeared. Stewart et al.[140] described a 16-year-old boy initially seen with severe aortic and mitral regurgitation who developed spondylitis and iridocyclitis 5 and 6 years later, respectively, as well as mild peripheral arthritis. Pelkonen et al.[141] described a 13-year-old boy with arthritis. A cardiac murmur was heard 15 months after the onset of the articular symptoms, and 8 months later the patient required surgery because of massive aortic regurgitation. Radiographic evidence of sacroiliitis was not detected until almost 4 years after the onset of his joint symptoms. In these five patients, there was no correlation between the type of joint presentation (peripheral arthritis versus root joints versus sacroiliitis) and the development of cardiac lesions. There was also a discrepancy in the severity of cardiac involvement among these patients. The presence of HLA-B27 was the only consistent feature. Aortic insufficiency has also been described in a young boy 32 months after the onset of Reiter's syndrome.[142] The apparent lower frequency of cardiac involvement in juvenile ankylosing spondylitis may reflect the fact that followup is of shorter duration than in adults. It seems prudent to advise that all children with a spondyloarthropathy be followed closely for the development of aortic insufficiency as they progress into adulthood.

Conduction Defects

Atrioventricular conduction disturbances occur in ankylosing spondylitis and are often associated with aortic valvular disease.[128–137] Weed et al.[132] estimated that 44% of ankylosing spondylitis patients with aortic insufficiency will have cardiac conduction defects, while 8% of ankylosing spondylitis patients without aortic insufficiency will have conduction defects. In any event, conduction defects appear more frequently in patients with ankylosing spondylitis than in the general population. Some studies suggest that the frequency of heart disease is greater when the spondylitis is severe and accompanied by peripheral arthritis or iritis,[128] while other studies suggest that heart disease can appear as a late manifestation of mild uncomplicated disease.[132] Conduction disturbances are rare in children with juvenile ankylosing spondylitis. Pelkonen et al. described a young patient with progressive lengthening of the P-R interval and rapid progression of aortic regurgitation.[141] The pathologic basis for the conduction disturbance in patients with ankylosing spondylitis is thought to be a result of extension of the fibrous process extending from the aortic root and valves and membranous ventricular septum into the muscular septum to interrupt or destroy the conduction fibers in the atrioventricular bundle or proximal bundle branches.[120,137] Some authors believe that electrocardiographic evidence of a conduction defect may provide an early indicator of aortic root disease.[132,141]

Conduction disturbances have also been described in patients with Reiter's syndrome.[143,144] First-degree heart block is the most common disturbance detected. It is usually transient and occurs during the active phase of illness. Some conduction abnormalities, however, appeared after a long latent period at a time when other manifestations of Reiter's syndrome were inactive. Complete AV block is a rare manifestation of this disease, and when it occurs it is usually after a long course of recurrent arthritis, iritis, urethritis, and dermatologic abnormalities. As in patients with ankylosing spondylitis, aortic regurgitation is often associated with complete AV block in Reiter's syndrome.

While conduction disturbances are rare in children with spondyloarthropathies, regular evaluations with electrocardiograms as they progress to adulthood may warn of future valvular involvement.

LYME DISEASE

In 1975, an epidemic form of pauciarticular arthritis was recognized in Old Lyme, Connecticut.[145] The disease is now known to be a complex multisystem disease involving the skin, joints, nervous system, and heart. It usually begins in summer with erythema chronicum migrans (ECM), the unique clinical marker for Lyme disease. The lesion begins as a red macule or papule that expands to form a large, annular lesion, usually with a bright red outer border, partial central clearing, and indurated center.[146] The lesion may occur anywhere, but the thigh, groin, and axilla are particularly common sites. The lesion resembles an arthropod bite. Within several days after the appearance of the initial skin lesion, many patients develop multiple annular secondary lesions. Skin involvement is often accompanied by systemic manifestations, including malaise, fatigue, fever, chills, generalized achiness, and regional lymphadenopathy.[146,147] In addition, some patients may have evidence of meningeal irritation, mild encephalopathy, mi-

grating musculoskeletal pain, hepatitis, generalized lymphadenopathy or splenomegaly, sore throat, nonproductive cough, or testicular swelling.[148]

Neurologic manifestations may appear while ECM is present or several weeks after it fades, and may include aseptic meningitis, encephalitis, chorea, cerebellar ataxia, cranial neuritis (including bilateral facial palsy), motor and sensory radiculoneuritis, mononeuritis multiplex, and myelitis.[149]

About 60% of patients develop arthritis within a few weeks to years after the onset of illness.[146] Early in the illness, patients may complain of migratory musculoskeletal pain, often without actual joint swelling. The arthritis does not usually appear until months to years later. It is at this time that patients are often misdiagnosed as having juvenile rheumatoid arthritis, especially if the early symptoms are not recalled.

Cardiac Manifestations of Lyme Disease

In patients with Lyme disease, the incidence of cardiac involvement has been estimated to be 8%.[150] Steere et al.[151] described 20 patients with Lyme carditis. The most common finding was atrioventricular block, including 10 patients with high degree AV block (complete in eight, Wenckebach in two) and eight patients with first-degree block. All patients with high degree AV block were symptomatic with syncope, dizziness, shortness of breath, and/or chest pain. The degree of AV block often fluctuated rapidly; in all patients with complete AV block, first-degree and Wenckebach-type second-degree block were also seen. Some patients went from first-degree to complete AV block and back within minutes. In all patients, the AV block appeared proximal to the bundle of His. Some patients have evidence of more diffuse cardiac involvement, including electrocardiographic changes compatible with acute myopericarditis, radionucleotide evidence of myocarditis, or, rarely, cardiomegaly, pleural effusions, or pancarditis.[151–153] The duration of cardiac involvement is usually brief (3 days to 6 weeks), but it may recur.[148] Some patients have required temporary transvenous pacemakers.[153] On rare occasions, Lyme carditis may occur in the absence of other clinical symptoms.[154]

Laboratory Findings

Etiologic Agent

Lyme disease is now known to be caused by a newly recognized spirochete that has characteristics of both treponemes and borreliae,[155,156] and has been named Borrelia burgdorferi.[157] It is transmitted by the tick Ixodes dammini. The organism has been recovered from skin, cerebrospinal fluid, joint fluid, and cardiac myocardium from patients with Lyme disease.[153,155–158] The principal endemic areas are the coastal northeast and western states, Minnesota and Wisconsin; however, cases have been reported in other states as well as in Europe. The peak onset is usually in the summer. The principal animal hosts for the tick are mice and deer.

Antibody Titers

Specific IgM antibody titers against the I. dammini spirochete usually reach a peak between the third and sixth week after the onset of disease; specific IgG antibody titers rise slowly and are generally highest months later, when arthritis is present.[155] The presence of antibody titers against this spirochete are useful in differentiating Lyme disease from other rheumatic illnesses.

Other Laboratory Findings

Early in the course of the illness the sedimentation rate is usually elevated.[146,147] Liver function tests may be abnormally elevated, especially when ECM is present.[147] Circulating immune complexes are present in most cases at the onset of ECM and may persist in patients with subsequent nerve or heart involvement.[159] In contrast, in patients with only subsequent arthritis, immune complexes usually disappear from the serum within 3 months. The finding of elevated serum IgM levels and cryoglobulins containing IgM may predict subsequent nervous system, cardiac, or joint involvement.[160]

Differential Diagnosis of Lyme Disease

ECM is the unique clinical marker for Lyme disease and, when present in its classic form, is diagnostic of Lyme arthritis.[148] The lesion, however, does not always take on its classic appearance or may be forgotten by the time subsequent sequelae of the disease appear.

The early manifestations of Lyme disease (especially severe headaches and stiff neck, abdominal symptoms, and lymphadenopathy) may be confused with viral infections, especially when ECM is absent or missed or is not the first manifestation.[148]

The later manifestations may be confused with several immune-mediated illnesses. Acute rheumatic fever should be considered in the differential diagnosis.[151] The Jones' major clinical criteria for rheumatic fever include carditis, arthritis, chorea, erythema marginatum and subcutaneous nodules. Except for erythema marginatum, which superficially resembles ECM, the remaining manifestations may be seen in both rheumatic fever and Lyme disease. The carditis of Lyme disease, however, affects adult men more frequently than children, and, in addition, does not usually affect the valves. The most frequent cardiac involvement in Lyme disease is complete AV block with mild myopericardial involvement. The arthritis may be similar in Lyme disease and rheumatoid arthritis, but commonly recurs for several years in Lyme disease. An important distinction between these two diseases is the possibility of other neurologic involvement (headache, stiff neck, frank meningoencephalitis) that may accompany cardiac involvement in Lyme disease.

Children with chronic arthritis are often misdiagnosed as having juvenile rheumatic arthritis (JRA); however, several distinctions may be made. The classic picture of ECM and the rheumatoid rash of JRA are dissimilar. While complete AV block is the most common cardiac manifestation of Lyme disease, it is an extremely unlikely accompaniment to JRA. Instead, pericarditis is the most common cardiac manifestation of JRA (see the section on JRA).

Yersinia enterocolitica may cause valvulitis, myopericarditis, and polyarthritis and may be confused with Lyme disease.[151] Unlike Lyme disease, however, diarrhea and abdominal pain are characteristic, cardiac conduction abnormalities are unusual, and the only associated skin manifestation is erythema nodosum.

Treatment of Lyme Disease

ECM responds promptly to therapy with penicillin or tetracycline.[151] Steere and Malawista[148] recommend that when patients are early in the course of illness, adults receive oral tetracycline, 250 mg four times a day for at least 10 days. Phenoxymethyl penicillin, 500 mg four times a day for the same duration, or 2.4 million units of benzathine penicillin intramuscularly may be as

effective. In children, they recommend phenoxymethyl penicillin, 50 mg per kg per day (not less than 1 gram per day or more than 2 grams per day) in divided doses for 10 to 20 days, or in the case of penicillin allergy, erythromycin, 30 mg per day, in divided doses for 15 or 20 days.

In patients with frank meningitis, spinal pleocytosis, and cranial or peripheral neuropathies, they recommend intravenous penicillin G, 20 million units a day in divided doses for 10 days.[148]

Established Lyme arthritis can also be treated with high-dose penicillin.[148] Regardless of antibiotic therapy, the duration of heart involvement is usually brief. Steere et al.[151] are uncertain of the advisability of prednisone for heart involvement. Because the first patient who received it improved, subsequent patients in that study with high-degree AV block were also so treated. All had improvement in the degree of block within 24 to 48 hours, and all except one had complete resolution within 1 to 2 weeks. The major disadvantage of prednisone was that because of recurrent nervous system or joint involvement 2 to 4 months of therapy were usually needed before the medication could be stopped.

Steere et al. recommend that patients with high-degree AV block or first-degree block with PR intervals longer than 0.30 second be hospitalized because of the marked risk of developing complete AV block.[151] In patients with complete AV block they advise therapy with a temporary pacemaker and aspirin. They recommend treatment with prednisone if the patient also demonstrates meningoencephalitis, complete AV block for longer than one week, or deterioration of cardiac status with cardiomegaly.

CHAPTER 89

Kawasaki Disease

Junichiro Fukushige
Michael R Nihill

Kawasaki disease was named for Dr. Tomisaku Kawasaki, who recognized and made the original report of this disease. It is a clinical entity of an acute febrile syndrome of unknown etiology, observed predominantly in children under 4 years of age. In addition to prolonged fever and exanthema, which are common clinical manifestations of the diseases of children, Kawasaki disease has been characterized by its risk of sudden death due to coronary arteritis accompanied by aneurysms and thromboembolism. With an increase in numbers of affected young children, it has become a worldwide problem.

HISTORY

In January 1961, Dr. Kawasaki saw a 4-year-old boy who had been suffering from fever persisting for 7 days. His cervical lymph nodes were swollen, minor bleeding was present from the fissurings of lips, the conjunctivae were injected, and exanthema covered his body. His palms and soles were erythematous with indurative edema. Later there was peeling (desquamation) from his fingertips. This boy was treated with penicillin and steroids. Fever subsided after 2 weeks duration and the other symptoms improved gradually. He was sent home after a 1-month hospitalization. In 1962, Dr. Kawasaki saw a total of six patients with the same clinical manifestations as the first 4-year-old boy. It was 2 to 3 years afterward that other Japanese physicians started to recognize this syndrome as a new clinical entity. Until then, it had been diagnosed as either exanthema multiforme exudativum, Stevens-Johnson syndrome, and/or juvenile rheumatoid arthritis.

In 1967, Dr. Kawasaki made a report on 50 cases of this rather unique syndrome as "febrile oculo-oro-cutaneo-acrodesquamatous syndrome with or without acute nonsuppurative cervical lymphadenitis."[1] In 1970, The Japan Mucocutaneous Lymph Node Syndrome (MCLS) Research Committee sponsored by the Ministry of Welfare was formed and the first national survey was conducted, revealing 26 in 1857 patients due to this disease, which was once thought to be benign.

The numbers of affected children continued to increase in Japan. There have been three nationwide outbreaks: in 1979 (6867 reported patients), 1982 (15,519 patients), and 1986 (12,847 patients). Although this disease is extraordinarily prevalent in Japanese infants and younger children living in Japan, cases have been increasing on a worldwide basis. In 1973, the first report of 8 cases of MCLS outside Japan was released from Korea,[2] followed by reports from the United States.[3–5] The publication by Dr. Kawasaki in an English journal[6] spread the information about this syndrome and accelerated its recognition. There have been reports from Canada,[7] Central and South America,[8] Europe,[9–12] Australia, and other countries throughout the world.[13–17]

EPIDEMIOLOGY

Incidence

According to the national epidemiologic surveys conducted in Japan, the number of the patients reached 83,857 (boys 48,570, girls 35,287) in Japan by the end of 1986, with 349 deaths (0.4%). In the United States, 2091 cases had been reported by the end of 1985.

Race

The majority of affected children have been Japanese or those with Japanese background. According to the report from the Centers for Disease Control (CDC), the incidence rate per year among children aged 8 or less living in the United States was nearly three times higher in Asian-American children than in black children, and more than six times higher in Asian-American than in white children. The incidence in Japan is greater than 40 cases per year per 100,000 children aged 4 years or less.

Sex

In Japan, the ratio of males to females of children with Kawasaki disease is about 1.4:1. Although it once had been reported as to be about 1.5:1, the numbers of affected female children have been increasing since 1979.[18] In the United States, it is about 1.67:1. Fatal cases of Kawasaki disease are also more common in males.

Age

Kawasaki disease is essentially found in infants and younger children. The youngest patient so far recognized in Japan was 35 days old at the onset. In Japan, about 1% of the patients are younger than 2 months or older than 9 years. The peak age is in the first year for both males and females.[19] In Japan and also in the United States, some adult cases have also been reported, but they are extremely rare.[3,7,20–23]

According to a recent report from Japan, 38% of deaths occur in infants 6 to 12 months of age, 68% in children less than 2 years old, and 78% in children less than 3 years old; 39% of deaths had their acute phase before 6 months of age.[18] In Japan, 349 death cases were reported by the end of 1986. There were 10 and 18 deaths in 1985 and 1986, respectively, showing the fatality rate by year of 0.1% for two consecutive years.

Geography

Kawasaki disease has been recognized worldwide and diagnosed in at least 27 countries. Next to Japan, the following countries are listed in descending order according to the numbers of recognized cases: Korea,[2] United States,[3–5] Canada,[7] West Germany, Finland, France, England, New Zealand, Australia, Taiwan, Sweden, Belgium, and the Netherlands. In all of the above countries, more than 10 cases have been reported.[18]

Season

In Japan, Kawasaki disease is seen year round. Although there were certain increases of patients from April to June in the two outbreaks in 1979 and 1982 in Japan, no clear pattern has been observed so far. In Korea, there have also been two outbreaks, from November 1979 to January 1980 and from May 1983 to September 1983.[18]

Communicability

There has been no evidence that Kawasaki disease is transmitted from person to person. In Japan, 1.5 to 2% of reported cases have been found in two siblings, and 50% of them had the disease occur within 7 days of the other.[18,24] The percentage is certainly too high to be due to chance, but at the same time, it is too low to accept as proof of an infectious etiology of this syndrome.[5] In Japan, there is a recurrence rate of 3%. One patient had the disease four times.

Clustering

In Japan and also in the United States, there has been a geographic clustering of cases, but the significance of this is still unknown. In 1979, local and temporal geographic clustering was noted starting from March in southern Japan to June in northern Japan. It is of interest to know that two outbreaks in Korea (1980, 1983) occurred approximately 1 year after outbreaks in Japan. Outbreaks have been also reported in several large American cities.[25,26]

PRESENTATION

Clinical

Diagnostic guidelines of Kawasaki disease (MCLS) were suggested initially in 1970 by the MCLS Research Committee. Since then, changes have been made. The present diagnostic guidelines are from the fourth edition revised in 1984 (Table 89–1).

High fever (approximately 39°C) is the initial symptom of this disease.[27] The fever persists for 5 or more days. The effect of antipyretics is temporary. In most of the cases, fever subsides in 1 to 2 weeks but in some cases, the patient becomes febrile again or even a third time after a 1- or 2-day afebrile period.

Erythema of the palms and soles with indurative edema of hands and feet are seen several days after the onset of fever (Fig. 89–1). Peeling or membranous desquamation of the fingertips and toes begins 10 to 15 days after the onset of the disease, when high

Table 89–1. Diagnostic Guidelines of MCLS

A. PRINCIPAL SYMPTOMS
1. Fever persisting 5 days or more
2. Changes of peripheral extremities:
   [Initial stage]: reddening of palms and soles, indurative edema
   [Convalescent stage]: membranous desquamation from fingertips
3. Polymorphous exanthema
4. Bilateral conjunctival congestion
5. Changes of lips and oral cavity: reddening of lips, strawberry tongue, diffuse injection of oral and pharyngeal mucosa
6. Acute nonpurulent cervical lymphadenopathy

B. OTHER SIGNIFICANT SYMPTOMS OR FINDINGS
The following symptoms and findings should be clinically considered:
1. Cardiovascular: auscultation (heart murmur, gallop rhythm, distant heart sounds), ECG changes (prolonged PR–QT intervals, abnormal Q wave, low voltage, ST-T changes, arrhythmias), chest x-ray findings (cardiomegaly), 2-D echo findings (pericardial effusion, coronary aneurysms), aneurysm of peripheral arteries other than coronary (axillary, etc.) angina pectoris or myocardial infarction
2. GI tract: diarrhea, vomiting, abdominal pain, hydrops of gallbladder, paralytic ileus, mild jaundice, slight increase of serum transaminase
3. Blood: leukocytosis with shift to the left, thrombocytosis, increased α2-globulin, slight decrease in erythrocyte and hemoglobin levels
4. Urine: proteinuria, increase of leukocytes in urine sediment
5. Skin: redness and crust at the site of BCG inoculation, small pustules, transverse furrows of the fingernail
6. Respiratory: cough, rhinorrhea, abnormal shadow on chest x-ray
7. Joint: pain, swelling
8. Neurological: pleocytosis of mononuclear cells in CSF, convulsion, unconsciousness, facial palsy, paralysis of the extremities

*With at least five of the six principal symptoms, or four associated with coronary lesions confirmed by two-dimensional echocardiography or angiography, diagnosis of MCLS can be established.

Fig. 89–1. Erythema of soles and polymorphous exanthema.

fever usually subsides (Fig. 89–2). In contrast to scarlet fever, it is restricted to the hands and feet.

A few days after the onset of fever, an erythematous rash of variable size develops predominantly over the trunk. The rash itself is not characteristic, however, it resembles that of measles of early stage (Fig. 89–3). Patients rarely complain of itching. Vesicles or crust formation are rare except for at the site of BCG inoculation. Within a few days after the onset of fever, the bulbar conjunctivae become hyperemic bilaterally (Fig. 89–4). Purulent conjunctivitis is a rare complication. The lips become reddish, dry, cracked, and sometimes hemorrhagic. A ''strawberry tongue'' appearance is usual (Fig. 89–5) and the oral mucosa is also hyperemic. By this time, when conjunctival congestion and polymorphous exanthema are also present, in most of the cases, the diagnosis of Kawasaki disease can be made. A ''toxic'' appearance of the patient with injected bulbar conjunctivae, bright red lips, and rash on the face are characteristic and impressive.

Fever for 5 or more days, polymorphous exanthema, conjunc-

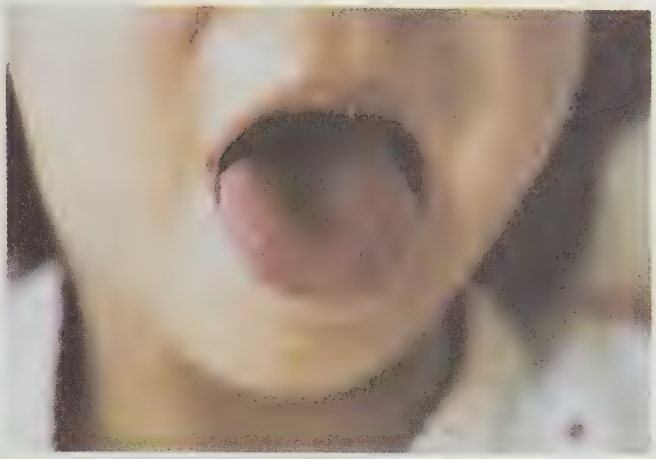

Fig. 89–5. Strawberry tongue.

tival congestion, and reddening of the lips are seen in more than 90% of patients. Nonsuppurative cervical lymphadenopathy is seen in about 70% of the cases, usually at an early stage. The lymphadenopathy is not always bilateral and may disappear quickly. Occasionally, a patient is misdiagnosed as having mumps due to the diffuse swelling of the submandibular area. Lymphadenopathy is restricted to the area around the neck.

Auscultation of the heart reveals a gallop rhythm and distant heart sounds in 80% of patients, usually in the second week of illness.[28] Rarely, a murmur of mitral regurgitation is heard. Cardiomegaly on chest roentgenography is seen in more than 30% of patients.

Watery diarrhea with mild abdominal pain and vomiting may appear in the early phases of the illness in 35% of patients. In patients with bloody stools, Yersinia infection must be ruled out as well as intussusception.[29] Frequent vomiting or meningeal signs necessitate lumbar puncture. Tenderness in the right upper quadrant could be due to a hydropic gallbladder, in which case echographic examination of the abdomen is indicated.[30–33] Reddening followed by crust formation at the site of BCG inoculation is a relatively early sign of Kawasaki disease, especially in infants within one year after the inoculation (Fig. 89–6). Sterile small pustules on or around the knees, elbows, genital area, and buttocks are occasionally seen in 3 to 10% of patients in the first to second week of illness. Large joint arthralgias and arthritis with pain and/or swelling may be noted but not frequently. Isolated facial palsy, hearing difficulty, unconsciousness, and paralysis of the extremities during the acute stage are rare complications.[34–36]

Fig. 89–6. Reddened skin at the site of BCG inoculation with small pustules.

Laboratory

Electrocardiographic changes include PR prolongation, low voltage, QTC prolongation, ST depression, and ST elevation[37,38] (Fig. 89–7). Low QRS voltage and ST depression are usually seen in the first week of illness in 6 to 43% of patients and 23 to 56%, respectively. In the second and third weeks of illness, PR prolongation, (41%), QTC prolongation (59%), and ST elevation (20%), are seen. Arrhythmias are rare and temporary. Development of paroxysmal supraventricular tachycardia, atrial fibrillation, ventricular tachycardia, and complete atrioventricular block are associated with serious coronary arterial lesions. Electrocardiographic changes are common in cases of patients with cardiomegaly, congestive heart failure, and heart murmur. An electrocardiogram should be recorded at least once per week during the acute phase of the disease.

Two-dimensional echocardiography is extremely useful to detect and follow the most serious complications of Kawasaki disease, i.e., aneurysms of the coronary arteries (see Complications, below)[39–46] (Fig. 89–8).

Leukocytosis with a shift to the left is a common finding. Leukocyte counts in excess of 20,000 per cu mm occur in about 25% of patients and in excess of 15,000 per cu mm in about 50%. Anemia occurs in about 50% of patients. The erythrocyte sedimentation rate is usually elevated as well as the $\alpha 2$-globulin level. C-reactive protein is positive in about 90% of patients. Thrombocytosis with platelet counts in excess of 500,000 per cu mm is a constant laboratory finding that develops in the second week of illness. Usually it persists for about 4 to 6 weeks. Leukocyte counts are increased in urine sediment and proteinuria is also common, but bacteria are rarely found in the urine.[4,47]

Pleocytosis of mononuclear cells in the cerebrospinal fluid (CSF) is a common finding but CSF glucose and protein are normal in almost 90% of cases. Aseptic meningitis, which usually develops within 10 days of illness when the patient is usually still febrile, is a rather frequent complication seen in 10 to 53% of

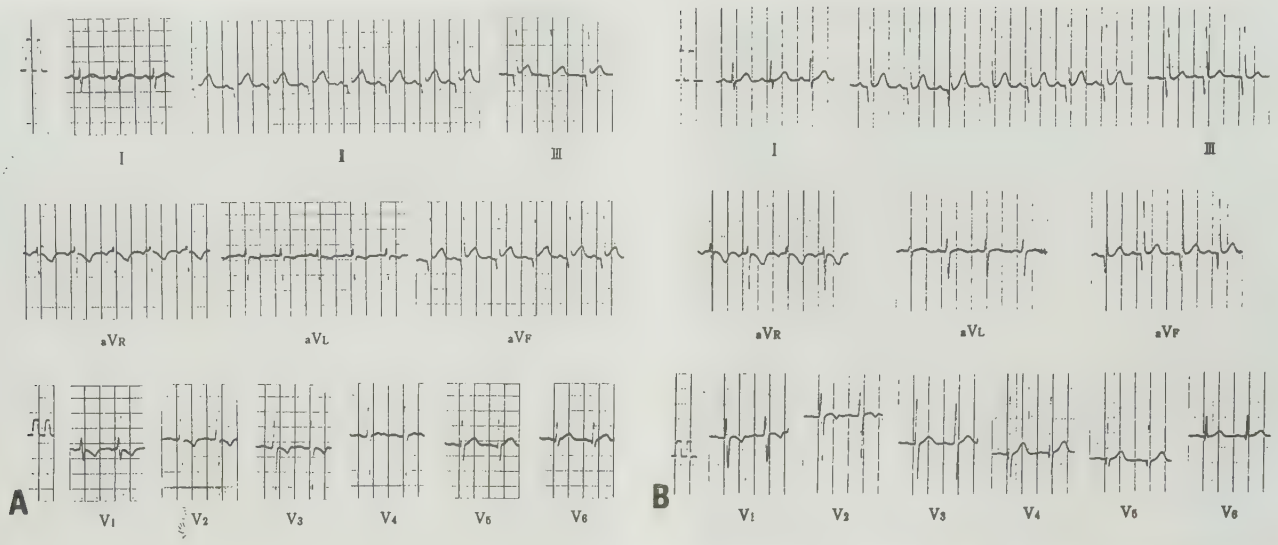

Fig. 89–7. Serial electrocardiograms of a 7-year-old asymptomatic boy who had Kawasaki disease at 5 months of age. His fever persisted for about 50 days. (A) Electrocardiogram at 2 months of illness when the patient was still febrile, reveals ST elevation in leads II, III, aVf. (B) Electrocardiogram at 3 years and 1 month reveals deep Q wave in lead III.

cases. Patients under 1 year of age are most susceptible; irritability and meningeal signs are usually mild. Electroencephalographic abnormality, i.e., diffuse slow waves, is frequently revealed in the acute state of the disease.

PATHOLOGY

The pathologic basis of this syndrome is an acute nonspecific, and systemic vasculitis. Since the majority of the victims of this disease died of coronary lesions, extensive studies have been done on the cardiovascular lesions of this syndrome and they have been classified into four stages according to the duration of illness.[48]

Stage I (days 0 to 12) is characterized by acute vasculitis of the microvessels and small arteries and by acute perivasculitis and endarteritis of the major arteries, especially of the coronary system. Stage II (days 12 to 25) is characterized by panvasculitis and aneurysm formation of the coronary arteries resulting in thrombus formation and local obstruction. In stage III (days 26 to 40), granulation of the medium-sized arteries, especially coronary arteries, and at the same time disappearance of inflammation in the microvessels and smaller arteries are evident. In stage IV (day 40 and beyond), scarring, thickening of the intima, calcification, thrombus formation, and recanalization in the major coronary arteries are noted (Figs. 89–8 and 89–9).

Arteritis is particularly severe and frequently observed in the coronary arteries[49–51] and iliac arteries, but major arterial branches of the aorta such as mesenteric, renal, celiac, subclavian, carotid, and hepatic arteries may also be involved[39–44,52] (Fig. 89–10).

Aneurysm formation in the major coronary arteries is the most characteristic finding of this disease. Clinically 10 to 20% of patients develop coronary lesions. Peripheral aneurysms are usually associated with coronary artery aneurysms. Interstitial myocarditis, pericarditis, inflammation of the sinoatrial node and atrioventricular conduction system, endocarditis and valvulitis were also present.[53]

The similarities of the clinical and pathological findings of MCLS to those of infantile polyarteritis nodosa (IPN) have been well accepted by numerous investigators.[49,51,54–61] It is also clear that the clinical, pathologic, and histologic findings in IPN and MCLS are quite dissimilar to those of polyarteritis nodosa of the adult type.

Most of the investigators would agree with our opinion that Kawasaki disease and IPN are the same disease, and if they are not the same, they are indistinguishable. The first nationwide survey on MCLS in 1970 disclosed 10 death cases in Japan. A postmortem examination had been performed in four patients and IPN was the initial histopathological diagnosis in all. Dr. Kawasaki himself reported two cases of fatal MCLS as IPN in 1970. MCLS was considered to be a self-limiting benign disease at that time.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of Kawasaki disease is entirely clinical and no specific diagnostic test is available. The diagnostic guidelines of Kawasaki disease prepared by the Japan Kawasaki Disease Research Committee (Table 89–1) and the diagnostic criteria from Centers for Disease Control (CDC) for Kawasaki disease are useful for establishing the diagnosis in cases with typical clinical features. The CDC criteria for Kawasaki syndrome are as follows: 1) fever lasting 5 or more days associated with at least four of the following five features—bilateral conjunctival injection; one or more changes of the mucous membranes of the upper respiratory tract, including pharyngeal injection, dry, fissured lips, and "strawberry tongue," one or more changes of the extremities, including peripheral edema, periungual desquamation, and desquamation of hands and feet; rash, principally truncal; cervical lymphadenitis; and 2) the absence of another known disease process that could explain the findings.[62] But the situation differs in the atypical or mild case since no pathognomonic laboratory features have been established.[63,64]

The differential diagnosis of Kawasaki disease includes scarlet fever, Stevens-Johnson syndrome, juvenile rheumatoid arthritis, sepsis, and others. Kawasaki disease often has been misdiagnosed

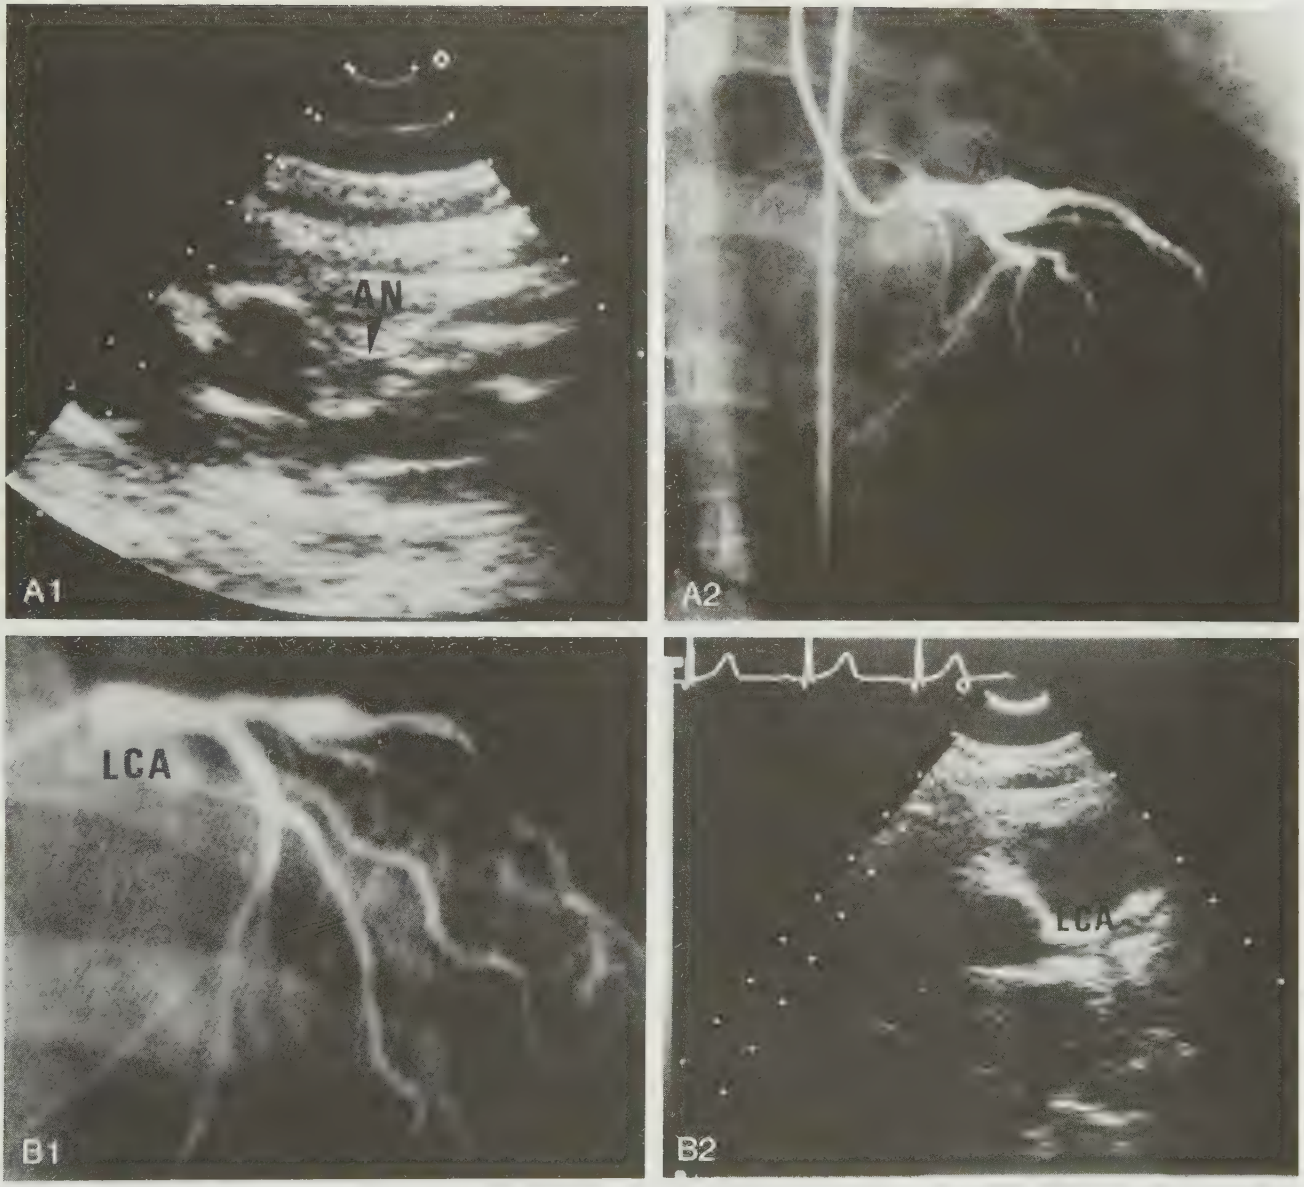

Fig. 89–8. Matching sets of two-dimensional echocardiograms and selective coronary angiograms from five patients. For each patient, the same view is shown for the echocardiogram and angiogram. The proximal part of the arteries are the sites of involvement in the majority of cases, but isolated peripheral abnormalities could also develop. Coronary artery findings can be classified into four categories, i.e., occlusion; stenosis, segmental and localized; aneurysm (AN), saccular and fusiform; and dilatation. AO = aorta, LCA = left coronary artery, RCA = right coronary artery.

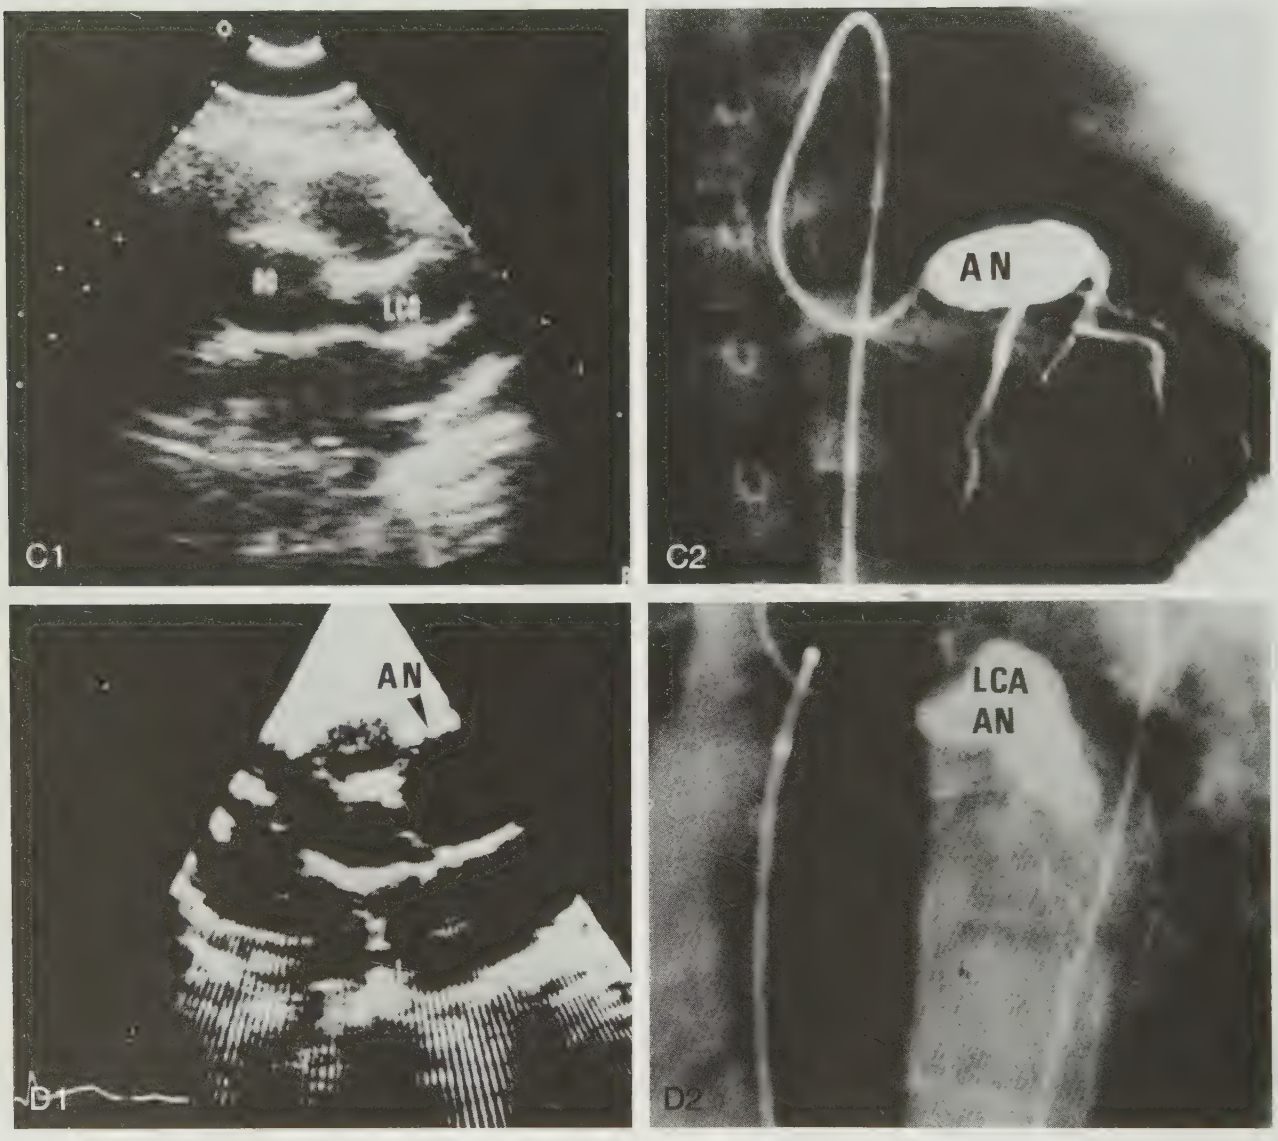

Fig. 89–8 *continued.*

Table 89–2. Etiological Agents of Kawasaki Disease So Far Proposed

Bacteria: Streptococcus, Streptococcus sanguis, Staphylococcus, Yersinia
Anaerobic propionibacterium
Fungi: Candida
Rickettsia or rickettsia-like bodies
Virus: EB virus, RS virus, Rotavirus, Herpesvirus, Retrovirus, Toxoplasma
Leptospira
Mite
Chemical substances: mercury, detergent, antibiotics

as scarlet fever or streptococcal infection because of the similarities of clinical manifestations such as fever, rash, strawberry tongue, cervical lymphadenopathy, and desquamation. But in scarlet fever, the rash is not polymorphous, conjunctival congestion is absent, desquamation is seen all over the body, and antibiotics are effective. Most importantly, scarlet fever is rarely seen in children under 3 years of age.

In earlier days many physicians diagnosed Kawasaki disease as Stevens-Johnson syndrome. Although a severe case of Stevens-Johnson syndrome with rash, purulent vesicles, and involvement of mucous membrane of various parts of the body is not difficult to diagnose, a milder form may be confusing. Acute-onset juvenile rheumatoid arthritis (JRA) is another important disease to be differentiated. In the early phase of the disease it is particularly difficult to distinguish the common symptoms such as fever, rash, and swelling of the joints of hands and feet. In JRA, the absence of conjunctival congestion, changes of lips, and desquamation in the convalescent stage are useful in establishing the diagnosis. To rule out septicemia is particularly important since adequate treatment with antibiotics is urgent.

Measles, rubella, and other viral exanthematous diseases require continued observation to differentiate them from Kawasaki disease; usually this is not difficult since the courses are different.

Children with Yersinia infection may meet the diagnostic criteria of Kawasaki disease.[29] Serum antibody titer and isolation of bacteria from the stool should establish the diagnosis. Other possibilities to be included are anaphylactoid purpura, staphylococcal scalded skin syndrome, leptospirosis, Rocky Mountain spotted fever[65] and other rickettsioses.[66,67]

ETIOLOGY

In spite of extensive research, the etiology of Kawasaki disease remains unknown. Several epidemics in the past, the high incidence among siblings, and geographic characteristics including clustering favor an infectious agent as the cause. But the preponderance of males and the high incidence among Japanese infants or those who have Japanese backgrounds are against an infectious etiology. Etiological agents of Kawasaki disease so far proposed are summarized in Table 89–2.

Among many bacteria, streptococcus is the one that has been most extensively investigated. Ueno and Matsumi[68] demonstrated elevation of cellular antistreptolysin O (ASO) and lymphocyte ASO during the acute stage. They proposed streptococcal exotoxin (SPE) as an agent but streptococci have not been isolated from the patients. Streptococcus sanguis, known as a causative agent of bacterial endocarditis, has been isolated from patients and their mothers, but its role as a causative agent in Kawasaki disease is not confirmed.

Yersinia pseudotuberculosis infection produces clinical symptoms similar to Kawasaki disease and it has been isolated from stool cultures in patients who were diagnosed clinically as Kawasaki disease according to the diagnostic criteria.[29] A significant titer change in agglutinating antibody was also confirmed in these patients. But that is not the case in all patients with Kawasaki

Fig. 89–8 ***continued.***

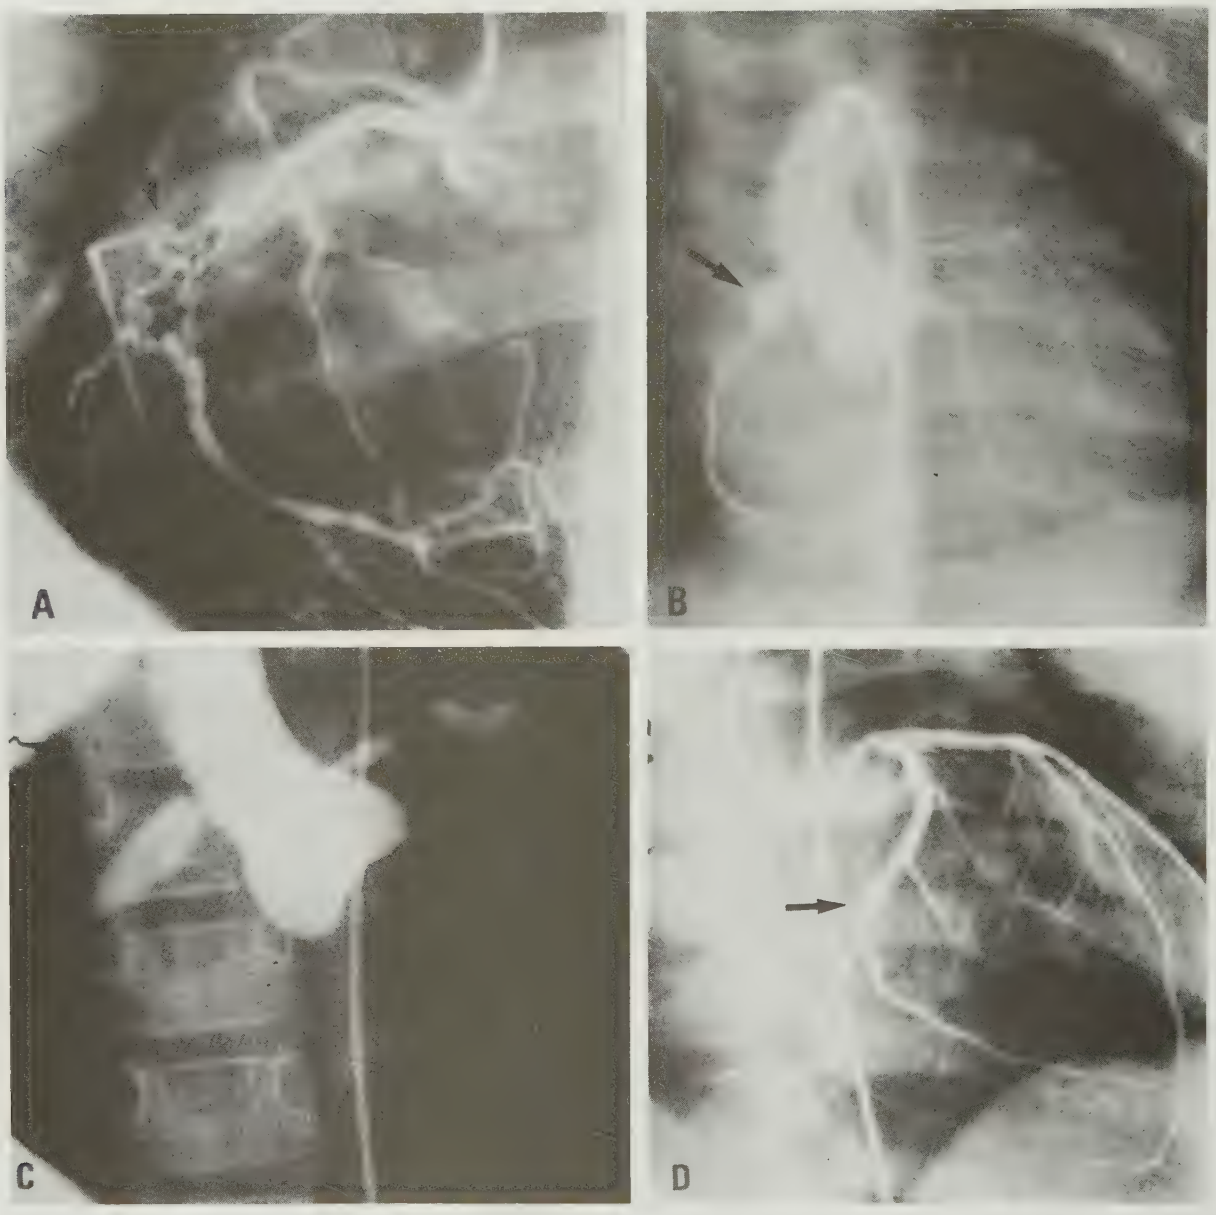

Fig. 89–9. (A) Selective right coronary angiography of an 8-year-old asymptomatic boy showing well developed collaterals and recanalization in the previously confirmed aneurysm. This patient had Kawasaki disease at 6 months of age. (B) Isolated saccular right coronary artery (RCA) aneurysm of a 9-month-old boy who had Kawasaki disease at 3 months of age. His fever persisted for more than 3 weeks. (C) Fusiform RCA aneurysm of a 5-year-old girl who had Kawasaki disease at 4 years, 2 months of age. Her clinical course was fair with fever lasting for 8 days. (D) Peripheral fusiform dilatation of the left circumflex coronary artery (LCX) of a 6-year-old boy who had Kawasaki disease at 1 year, 6 months of age.

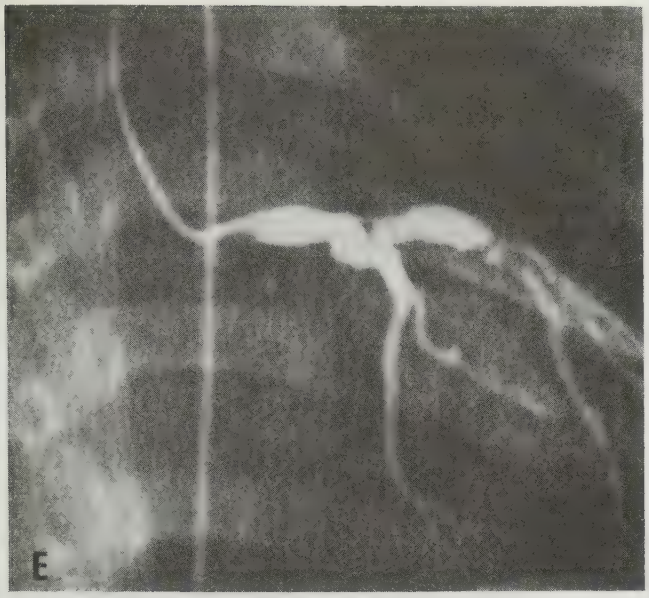

Fig. 89–9 *continued.* (E) Aneurysms with localized stenosis of a 3-year, 3-month-old boy who had Kawasaki disease at 11 months of age. He has been completely asymptomatic.

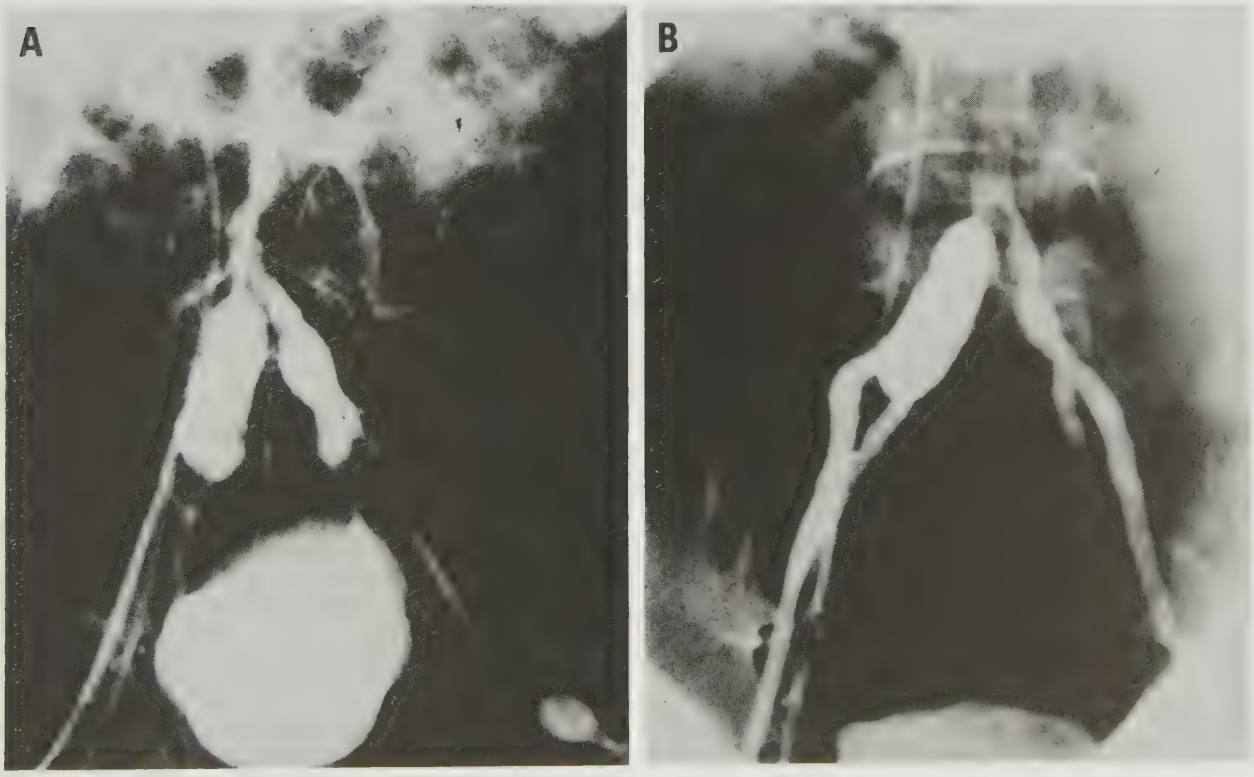

Fig. 89–10. Serial abdominal angiograms of the same patient as Figure 89–7. (A) At 3 months after onset of Kawasaki disease, there were multiple lesions involving abdominal aorta, renal, and bilateral iliac arteries. Both right and left femoral arteries were barely patent with isolated saccular aneurysm on the left. (B) Four years later, some degree of regression was confirmed and there was adequate flow through both femoral arteries.

disease. In Japan three children with Yersinia pseudotuberculosis infection who met the diagnostic criteria of Kawasaki disease were reported to have coronary aneurysms.

A variant strain of Propionibacterium acne,[69] staphylococcus, and salmonella[70] are also under consideration as causative agents, but no direct evidence has been demonstrated.

An abnormal immune response of the patient with Kawasaki disease to Epstein-Barr virus has been revealed.[71,72] According to Osato,[73] EB viral capsid antigen (VCA)-specific antibody responds positively in 93% of patients with MCLS within 3 months after the onset of acute stage, but titers are abnormally low. Rotavirus and common viruses such as adeno type 3 virus, herpes simplex virus, echo 11, HB antigen and most recently retrovirus[74] may play roles as causative agents, but again no single virus has been confirmed. Circulating immune complexes containing mite antigen have been demonstrated in the serum of patients[75–77] and intradermal reaction by mite antigen is positive in many of the cases. Certain mites were reported to be commonly found in the dust from the houses of patients, but case-control studies showed no difference in the number of mites.[78–80]

Although mercury poisoning (acrodynia) once was thought to be a pathogen of Kawasaki disease because of the similarities of the symptoms such as swelling, pink coloration and desquamation of the hands and feet,[81,82] patients with Kawasaki disease have had normal mercury levels and contents in hair and urine.[83,84] Other chemical substances so far proposed in relation to Kawasaki disease are antibiotics (tetracycline), detergents, and rug shampoo,[85] however, no associations have been confirmed. Thus the etiology of Kawasaki disease remains unknown.

COMPLICATIONS

Cardiovascular

Although it took several years after the original report by Dr. Kawasaki,[1] it has become quite obvious that the most serious complications of Kawasaki disease are cardiovascular. Cardiovascular involvement usually appears in the second week of illness when gallop rhythm, distant heart sounds, electrocardiographic changes, and cardiomegaly on chest roentgenography are often observed (Fig. 89–11). These findings progress in the second and third weeks of illness and except for severe cases, improve at the end of the fourth week.

Cardiovascular complications include arteritis and aneurysm formation of the coronary arteries, myocarditis, pericarditis, pericardial effusion, arrhythmias, and valvular disease.[8,10,36,64,86–94] Myocarditis, pericardial effusion, and valvulitis usually improve after about 1 month of illness in most of the cases; however, vasculitis of the coronary arteries follows a unique course. Dilatation of the coronary arteries due to vasculitis is recognized in about 50% of the patients beginning at 7 to 8 days of illness. The left coronary artery is involved in more patients than was the right, and the proximal parts of the left or right coronary arteries are most frequently involved. More distal parts of the coronary arteries are occasionally involved, making detection difficult by echocardiography. The dilatations or aneurysms remain even after the acute phase in 10 to 20% of patients. According to Kato,[94] of 713 patients who underwent aortography and/or coronary angiography at 1 to 3 months after onset of the disease, 161 (23%) had coronary aneurysms. Of 128 patients who were documented to have coronary aneurysms during the acute phase, angiographic findings became normal in 73 (57%), suggesting regression of the aneurysms in 1 to 2 years after the acute illness. In the remaining 55 cases, coronary artery lesions such as aneurysms, stenosis, obstruction, and irregular arterial walls persisted. Kamiya and Suzuki[95] have accumulated angiographic data on 1000 patients who were studied 2 years after the onset of the disease; 246 cases (25%) had coronary artery lesions; 154 of the 246 (63%) had aneurysms or dilatation, 60 (24%) had localized stenosis, 14 (6%) had segmental stenosis, and 18 (7%) had occlusion of a coronary artery. A giant coronary aneurysm with a diameter of 8 mm or more and saccular, sausage-shaped, or multiple aneurysms are considered to be important risk factors in the progression to stenosis or occlusion. Ischemic heart disease may develop in less than 3% of patients. Peripheral aneurysms in arteries other than the coronaries were usually found in patients with severe clinical symptoms of the acute phase and were usually accompanied by coronary lesions. According to Kato,[96] of 513 patients in his series 13 (2.5%) had peripheral aneurysms, axillary in 12 patients, iliac in 11, renal in 4, and internal thoracic artery in 3. Kamiya and Suzuki[95] also identified aneurysms and/or localized stenosis of the arteries other than coronary in 10 of 1000 cases (1%).

Diagnosis of coronary artery lesions in Kawasaki disease by two-dimensional echocardiography has been well established and its diagnostic sensitivity is reported to be 80 to 90%[39–46] (see Fig. 89–8). Use of a high-frequency transducer of 5 mHz is recommended as the patients are usually infants and younger children. Stenotic lesions may be detectable by echocardiography but in most of the cases are difficult to demonstrate. Prediction of the development of coronary lesions has been investigated. According to Asai et al.[97] who have proposed a ''score table'' for determining the indication for angiography, those patients with the following clinical symptoms and signs are likely to develop coronary artery involvement:

1. male infant less than 1 year of age
2. prolonged fever for more than 16 days or recurrent fever
3. peripheral white blood cell count greater than 30,000 mm
4. erythrocyte sedimentation rate (ESR) greater than 101 mm/hr
5. elevated ESR or C-reactive protein titer for more than 30 days of illness
6. reappearance of elevated ESR or C-reactive protein titer
7. electrocardiographic abnormality (abnormal Q wave in leads II, III, aVf)
8. symptoms of myocardial infarction

Koren[98] found from the Asai et al. data on 163 patients with Kawasaki disease that fever lasting for more than 14 days can be used as a single criterion in predicting risk of coronary disease, that coronary artery involvement occurred with equal frequency in boys and girls, and that there was no significantly greater incidence of coronary artery involvement in infants younger than 1 year of age.

For the early prediction of coronary involvement while the patient is still febrile, Burns et al.[99] have suggested elevated plasma β-thromboglobulin as a sensitive means of differentiating patients with coronary aneurysms from those with normal coronary arteries. Other investigators[26,100] have pointed out hypoalbuminemia as a predicting factor of coronary involvement. Regardless, frequent

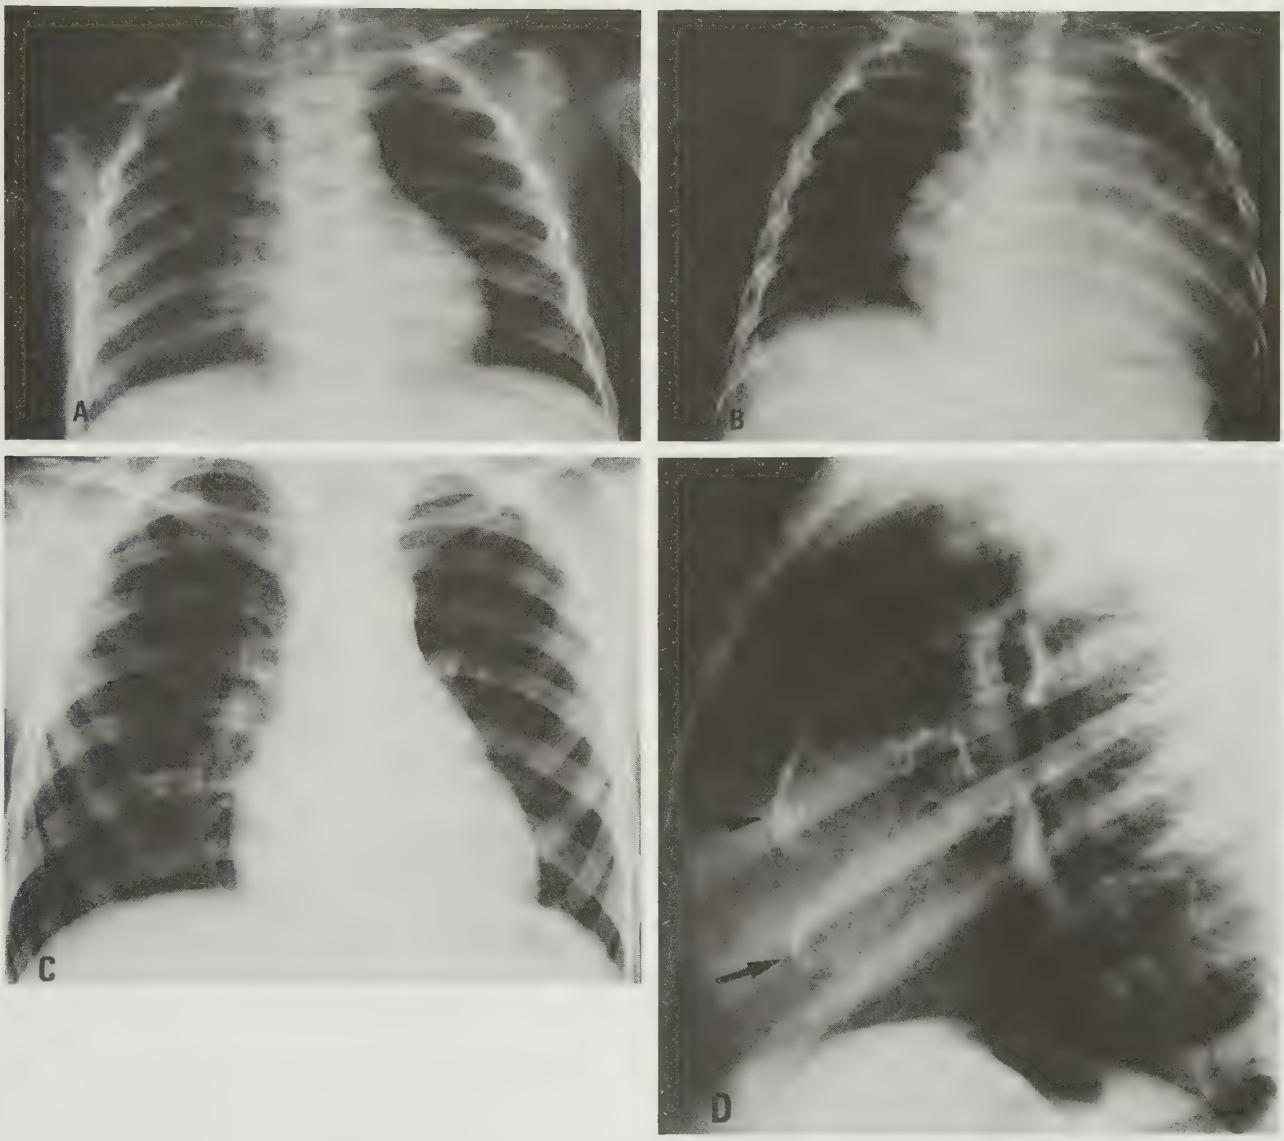

Fig. 89–11. Serial chest roentgenographs of the same patient as in Figure 89–7. Two PA views were taken in the acute phase. At the onset of fever (A), there were no abnormal findings. However, 3 weeks later he developed marked cardiomegaly (B). Now, at 7 years of age, on both PA (C) and lateral (D) views, calcified multiple giant coronary artery aneurysms are recognized. His myocardial scintigram shows no remarkable changes.

and serial two-dimensional echocardiography is indispensable in evaluating cardiovascular lesions.

The role of selective coronary angiography in evaluation and management of patients with Kawasaki disease is controversial. Although the proximal part of the left or right coronary artery where lesions are detected by echocardiography is more frequently involved, aneurysm or dilatation can develop in the more distal part of the coronary arteries and normal echocardiographic appearance of the proximal right or left coronary arteries may not rule out the involvement of the more distal part of the coronary arteries. In addition, the majority of cases with coronary artery lesions have normal electrocardiographic, chest roentgenographic, and also auscultatory findings. It has been generally considered reasonable to perform coronary angiography in patients known to have coronary lesions. Kamiya and Suzuki[95] from their experiences of selective coronary angiography on 1000 cases recommended repeating the study 1 year later on patients in whom coronary artery involvement was detected at the first study. Of 190 cases restudied after 1 year, in 29% aggravation of the stenotic lesion was recognized, and in 61% aneurysms decreased in size. There were no serious complications of coronary angiography.

Pericarditis, usually with a small amount of pericardial effusion, occurs in about 30% of patients in the first to second week of illness.[101] Rarely it progresses to cardiac tamponade and pericardiocentesis may be necessary. Usually no specific treatment is needed.

Mitral regurgitation due to valvulitis or ischemia of the papillary muscle is observed in about 1% of patients with Kawasaki disease in the acute phase.[53,102] Usually it is mild and disappears, but in rare cases it causes congestive heart failure and requires digitalis, diuretics, and vasodilators.[103] Infrequently, aortic or pulmonary regurgitation develops due to valvulitis.[101]

Myocardial infarction due to thromboembolic occlusion of aneurysms or progression of the stenotic lesions accounts for the majority of the causes of death due to Kawasaki disease.[18] Analysis of 104 deaths in Japan revealed that more than half of the patients (60 cases, 57%) died of acute myocardial infarction while 7 patients (9%) died of congestive heart failure after myocardial infarction. Analysis of 195 cases complicated with myocardial infarction collected in Japan revealed that attacks of infarction developed within 1 year of onset in 142 patients (73%), more frequently within 3 months in 77 cases (40%); 43 patients (22%) died from the first attack and 26 of 43 (61%) had sudden death (death within 24 hours after the attack). Asymptomatic myocardial infarction was recognized in 73 patients (37%); chest pain is more frequently observed in children over 4 years of age (Figs. 89–12 and 89–13).

Other Complications

Complications involving liver and biliary tract are classified into three categories:

1. primary liver dysfunction due to Kawasaki disease itself,
2. hydropic gallbladder or acute cholecystitis,
3. secondary liver dysfunction induced by drugs.

Primary liver dysfunction characterized by elevated transaminases but not bilirubin in the first week of illness has been recognized in 17 to 26% of patients. At this point patients usually have not received any specific drugs, including aspirin. The development of hydropic gallbladder has been attributed to edematous change of the common bile duct due to vasculitis of the bile duct system

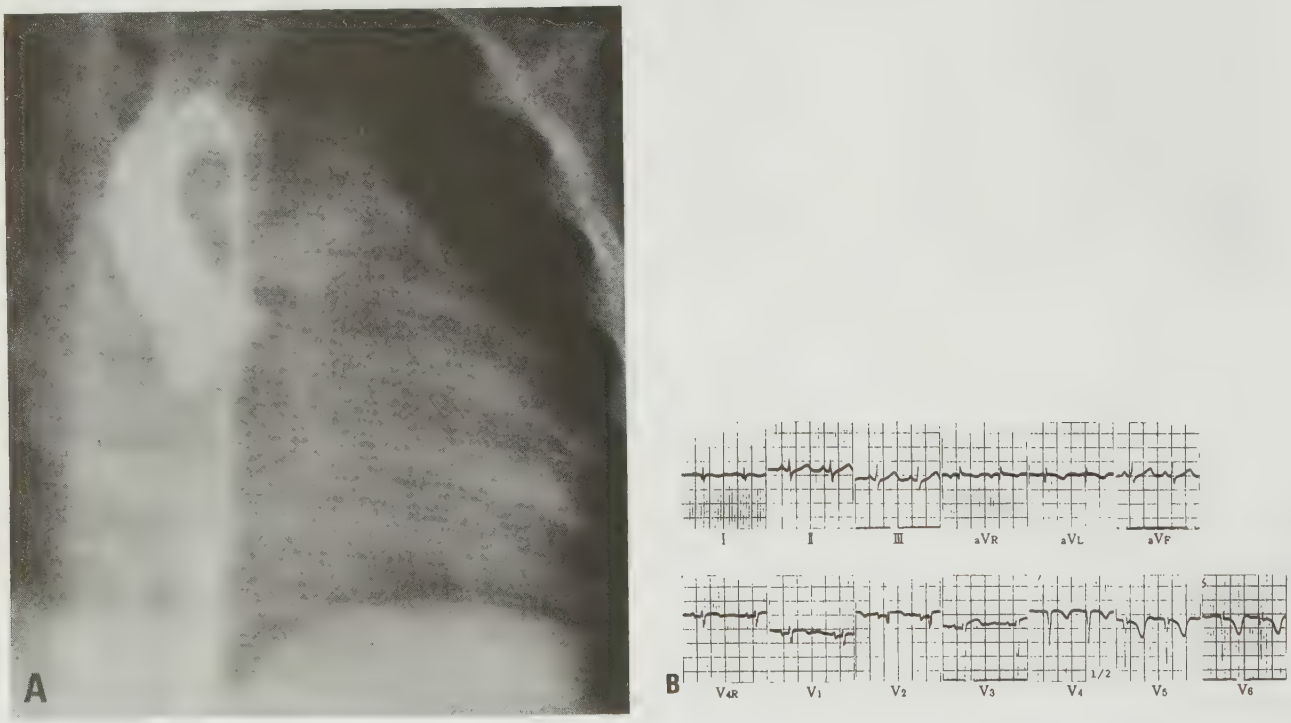

Fig. 89–12. Aortic root angiogram (A) and an electrocardiogram (ECG) obtained from a 2-years, 1-month-old patient, (B) 12 months after the onset of Kawasaki disease. Bilateral coronary artery aneurysms on angiogram and evidence of anterolateral myocardial infarction on ECG are recognized. Physical examination revealed mitral regurgitation of moderate degree.

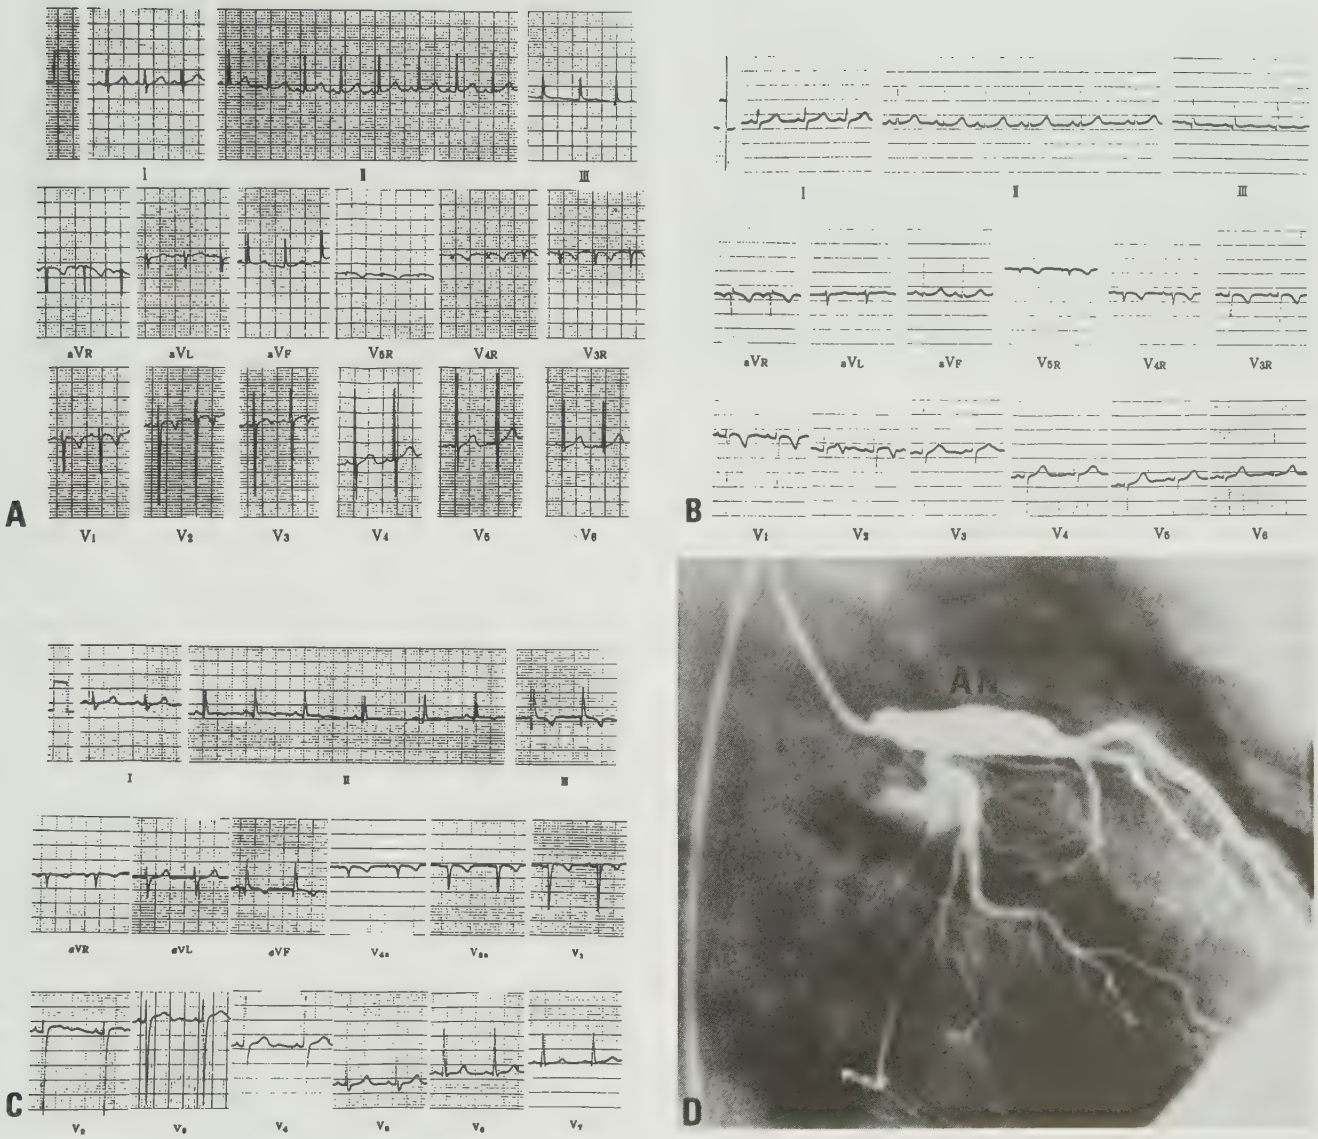

Fig. 89–13. Serial electrocardiograms of an 8-year-old girl who had Kawasaki disease at 2 years of age. At 7 years of age, she developed myocardial infarction but the symptoms were fairly mild, with abdominal pain and vomiting several times, which improved within a few hours. Compared to the tracing at 2 years, 10 months of age (A) and also at 4 years, 9 months of age (B), at 8 years ST-T changes in leads II, III, aVf, and q wave in leads III and aVf are obvious (C). D. Followup angiograms showed complete obstruction of the right coronary artery (RCA) at the orifice. There was late filling of RCA through collaterals from the left coronary artery (LCA). Ejection fraction by cineangiography was also abnormally low with 37%.

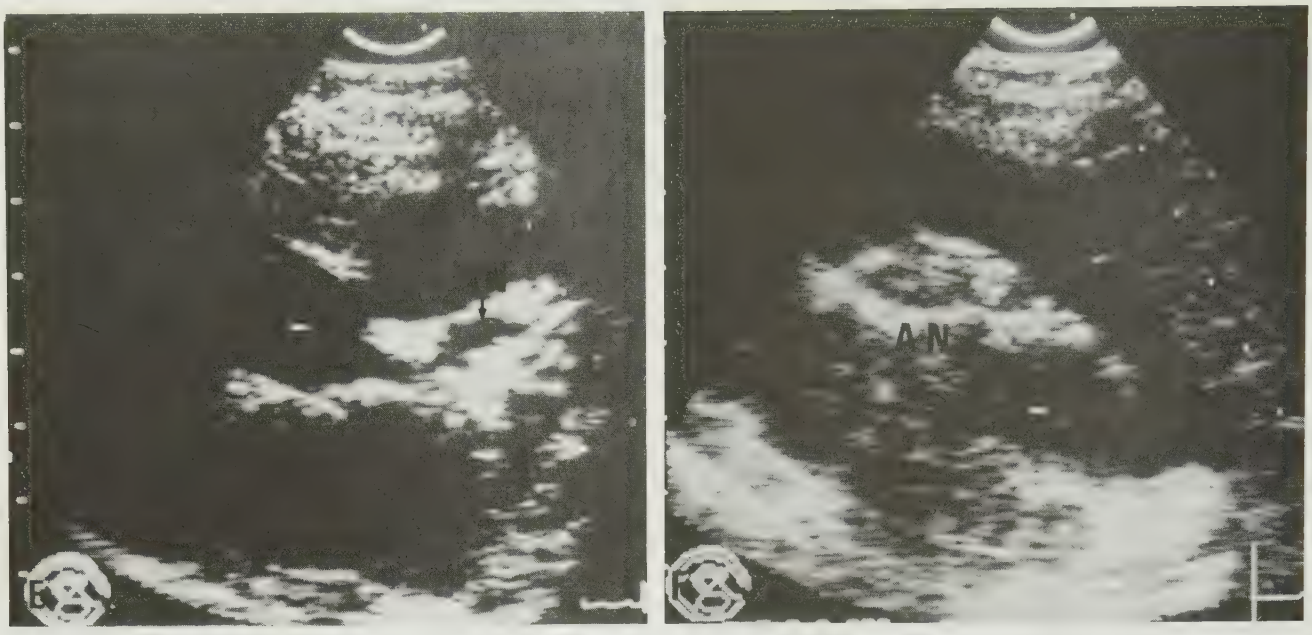

Fig. 89–13 *continued.* Two-dimensional echocardiograms showed aneurysmal change of LCA with dense echoes around the aneurysms indicating thickened arterial wall (E) and probable thrombi in RCA aneurysm (F).

including the gallbladder. In typical cases, a hydropic gallbladder is observed by ultrasonographic examination around 7 days of illness.[30–33] Laboratory examination reveals the pattern of obstruction of the biliary tract; elevated transaminases and bilirubin, elevated serum levels of total cholesterol, leucineaminopeptidase (LAP); and γ-glutamyltranspeptidase.

Patients with a hydropic gallbladder usually complain of abdominal pain or tenderness in the right upper quadrant, occasionally with vomiting and/or diarrhea. Hydropic gallbladder has been recognized in about 10% of patients with Kawasaki disease, more commonly in males.[8] About half of the cases have been seen in children over 5 years of age. Patients usually improve from this condition within 1 to 2 weeks, but rarely develop serious complications.[104,105] Liver dysfunction induced by aspirin has been well recognized.[106] Serum transaminases begin to elevate after 5 days to 2 months of administration but normalize within 1 to 2 weeks after cessation of aspirin.

Otitis media and aseptic meningitis are conditions commonly seen during the course of the illness. Other complications include moyamoya disease, Perthes' disease, ileus, nephritis and nephrosis, iritis, protein-losing enteropathy, pleural effusions, and urethritis; but all these conditions have been uncommon.

TREATMENT

Before 1977, Japanese physicians used mainly corticosteroids (prednisolone 2–4 mg per kilogram per day) since they seemed to be effective for fever and other clinical symptoms. Antibiotics were also given simultaneously. But a study on the effect of treatment on coronary artery involvement by Kato[107] showed that coronary angiography 1 to 2 months after the onset of disease demonstrated significantly increased incidence of coronary aneurysms in patients treated with steroids compared to those patients treated with antibiotics alone or aspirin. Since then treatment with corticosteroids has been abandoned in most of the centers taking care of large numbers of children with Kawasaki disease.[108] Japanese investigators have compared aspirin, flurbiprofen, and prednisolone plus dipyridamole in a total of 306 hospitalized patients with Kawasaki disease.[109] Coronary lesions were recognized at 1 month of illness in 22% of patients treated with aspirin, 39% with flurbiprofen, and 27% with prednisolone and dipyridamole. At 1 year after the acute illness, coronary artery abnormalities were observed in only 1% of cases treated with aspirin, but in 12% of cases with flurbiprofen and in 9% with prednisolone and dipyridamole. Aspirin is the most commonly used drug for Kawasaki disease at the present time. A recent survey in Japan revealed that almost 90% of patients with Kawasaki disease have been treated with aspirin.

Cases treated with a high dose of intravenous gammaglobulin have been increasing in both Japan and the United States. According to a nationwide survey in Japan, gammaglobulin was administered to 39% of patients in 1986 while to only 3% in 1982. Furusho and his colleagues[110,111] have evaluated immunoglobulin treatment for Kawasaki disease. In 6 of 40 cases (15%) treated with aspirin plus intravenous gammaglobulin (more than 1000 mg/kg), coronary artery lesions were detected by two-dimensional echocardiography within 29 days of illness, compared to 19 of 45 cases (42%) treated with aspirin alone.

The multicenter study by Newburger et al.[112] concluded that high-dose intravenous gammaglobulin (400 mg per kg of body weight per day for 4 consecutive days plus aspirin 100 mg per kg per day) is safe and effective. But still in 6 of 75 patients (8%) at 2 weeks and in 3 of 79 (4%) at 7 weeks after treatment with the above protocol, coronary artery abnormalities were recognized.

Further investigation is necessary to determine the minimal effective dose, frequency, and duration of treatment with gammaglobulin. Most importantly, long-term evaluation of the patients who had received high-dose intravenous gammaglobulin is needed. The mechanism by which high-dose intravenous gammaglobulin reduces the development of coronary artery lesions is

speculative. According to Leung,[113–115] in the acute phase of Kawasaki disease a decrease in suppressor T-cell activity for immunoglobulin production occurs. This can be normalized by a course of intravenous gammaglobulin for 4 days.

Recommended Treatment

Acute Phase (in Hospital)

Aspirin should be given once the clinical diagnosis of Kawasaki disease is suspected. Most Japanese pediatricians use a daily dose of 30 to 50 mg per kg of body weight divided in 3 doses. In the United States, however, an initial dose of 80 to 150 mg per kg per day has been recommended for 2 weeks or until the fever disappears.[116]

A controlled prospective study is needed to decide whether the use of high-dose aspirin is necessary or not. Monitoring of the blood salicylate level is recommended to avoid salicylate toxicity since during the acute phase, there seems to be malabsorption of aspirin. In Japan, low-dose aspirin has been effective in decreasing the incidence of coronary artery abnormalities. Most Japanese physicians continue daily aspirin (30 mg per kg) until the end of the second month, regardless of coronary artery involvement. In the United States, however, aspirin is reduced to 30 mg per kilogram per day once the fever disappears, and usually is continued until the end of the fourth week. Hospitalization and bedrest are the general rules for children in the acute phase. Therefore, our patients stay in the hospital at least for 3 to 4 weeks after the onset. As to the use of high-dose intravenous gammaglobulin, we think that severely ill patients are candidates at the present time, although in the United States, Newburger et al.[112] have recommended that all children with Kawasaki disease receive this form of therapy.

Most infants and children at this stage are markedly irritable and have a poor appetite. Intravenous fluid therapy is usually necessary. Once the fever disappears, patients feel comfortable and their appetite improves. Even so, the second and the third week of illness are the most critical period since patients are at the highest risk of coronary embolism, myocardial infarction, and death. Sudden onset of shock, pallor, vomiting, severe crying, dyspnea, chest pain, and convulsion were the documented symptoms at the time of death in 104 cases in Japan. When symptoms of myocardial infarction are noted, oxygen, vasodilators (nitroprusside, nitroglycerine), and catecholamines (dopamine, dobutamine) may be required. Anticoagulation with heparin and urokinase is advised, and if necessary, direct infusion of urokinase into the coronary arteries may be considered. Defibrillation, cardiac pacing, and/or administration of antiarrhythmic drugs such as lidocaine (Xylocaine) may be indicated.

Otherwise, in the hospital, except for daily checks of physical findings especially related to the cardiovascular system, we recommend weekly (or preferably twice weekly) determination of: CBC, platelet count, C-reactive protein titer, ESR, serum transaminases, serum protein, A/G ratio, urinalysis, BUN, creatinine, electrocardiogram, chest roentgenogram, and two-dimensional echocardiogram. If coronary or peripheral artery abnormalities are detected in the acute stage, dipyridamole (3 to 5 mg per kg per day) may be added to the usual dose of aspirin.

Patients are discharged when the clinical manifestations disappear, the hematological and serological findings improve, and the electrocardiographic and chest roentgenographic findings normalize. Patients may be discharged with coronary artery abnormalities unless there is evidence of embolism or infarction.

Subchronic Phase

We discontinue aspirin after 2 months in patients without coronary lesions as confirmed by two-dimensional echocardiography and/or cineangiography. Essentially no restriction of activities is necessary. Vaccination may be resumed after 2 months of illness. Although patients without sequelae are extremely unlikely to develop any signs or symptoms of cardiovascular abnormalities, we recommend yearly followup since any patient who has experienced Kawasaki disease in infancy may have a predisposition to development of atherosclerosis of coronary arteries in the early adult life. For those patients with coronary lesions after 2 full months of illness, we recommend continuation of antithrombotic therapy. A dose of 5 to 10 mg per kg of aspirin is administered once a day. In addition, dipyridamole (5 mg per kg per day in three doses) is often used. Since a single antithrombotic agent may be insufficient, combination therapy of aspirin and other drugs is recommended.[101,117,118]

Evaluations by electrocardiogram, chest roentgenogram, two-dimensional echocardiogram, and exercise test on a treadmill or bicycle once every 2 to 3 months should be planned. Blood samples should also be drawn to check for side effects of aspirin and other drugs.

Angiographic evaluation of coronary arteries is necessary in patients with cardiovascular sequelae although recent advances in echocardiography have enabled physicians to follow these patients noninvasively. We recommend performing selective coronary angiography on patients who have the following features:

1. Severe cardiovascular sequelae such as myocardial infarction, angina pectoris, valvular disease of moderate degree or more, and serious arrhythmias.
2. Persisting coronary aneurysms or dilatation by echocardiography beyond 6 months after the onset of the acute stage, but without any symptoms. Obstructive lesions should be ruled out in these patients.
3. When followup electrocardiography and/or exercise stress testing suggests myocardial ischemia, after echocardiography showed coronary aneurysms or dilatation during the acute stage, which regressed afterwards.

Symptoms such as chest pain or severe arrhythmias are signs that indicate a need for immediate angiographic evaluation. In those patients with cardiovascular sequelae documented by echocardiography but without any symptoms, coronary angiography may be scheduled between 6 to 12 months after the onset. Evaluation only by echocardiography may be misleading. Often, especially in patients with severe cardiovascular sequelae, angiographic evaluation should be repeated at certain intervals.

As described before, regression of coronary lesions is expected, especially in patients with mild fusiform dilatation and a diameter less than 8 mm. Generally, no restriction of daily activities is necessary in patients with coronary abnormalities but without obstructive lesions; however, hard exercise such as short dash, marathon, and competitive sports should be individualized. Those patients with obstructive lesions may be asymptomatic or may

suffer from angina pectoris, myocardial infarction, and even sudden death. Antithrombotic therapy is absolutely indicated but dipyridamole may not be indicated in cases with severe obstructive lesions of the coronary arteries since it may induce coronary steal. Patients with angina pectoris may be treated with calcium antagonists, beta-blockers, and nitrites or may require coronary bypass surgery. More recently, percutaneous transluminal coronary angioplasty has become a popular treatment for adults with coronary disease; it is possible this may be applied to children. Patients should be followed closely with electrocardiography, two-dimensional echocardiography, exercise stress test, thallium myocardial scintigraphy, and coronary angiography.

The followup interval depends on the condition of the individual patient. Some require weekly check-up, some monthly or quarterly. Daily activities of the patient with obstructive lesions should be determined according to the clinical symptoms and the result of the various tests mentioned above.

Coronary artery bypass surgery is considered in patients with the following features.[101,118–123]

1. Severe occlusion of the left main coronary artery or of more than one vessel,
2. severe occlusion in the proximal portion of the left anterior descending artery and poor collateral circulation.

An autologous great saphenous vein or internal mammary artery may be used for grafting. In view of the longterm patency of the grafts, the use of internal mammary artery may be preferred.[124] According to the experience on 55 surgically treated children collected in Japan, 31 patients improved but 5 patients died after surgery.[125,126]

For those patients with a history of Kawasaki disease, we recommend followup by a pediatric cardiologist. Examination should include precise history and physical examination, chest roentgenography (both anteroposterior and lateral views), exercise electrocardiogram, and two-dimensional echocardiography (Figs. 89–8, 89–11, 89–13, and 89–14). Some patients may need to be studied by angiography. Some may have a murmur of mitral regurgitation, calcification of the coronary aneurysms, and/or ECG abnormalities such as deep Q waves and ST-T changes.

FUTURE

The fatality rate of Kawasaki disease in Japan averages 0.5%, although it was reported initially to be 1.7%.[127] Therefore, in almost 99% of patients, at least the short-term prognosis is quite promising.

Problems arise about the possible long-term effects of vasculitis and aneurysm formation of the coronary arteries.[128] Regression of the coronary artery lesions of Kawasaki disease are well known but it is doubtful whether the coronary arteries become completely normal from the pathological point of view. Tanaka[49] reported residual coronary artery lesions in a child who was supposed to have had no coronary abnormalities in the acute phase. Those patients without documented sequelae have to be followed.[129,130]

Concerning the treatment and management, the main problems are

1. there has been no specific treatment regimen,
2. prediction in early active phase of the disease of eventual coronary artery lesions is extremely difficult, and
3. the question remains unanswered as to whether rapid improvement of the clinical manifestations with the use of high-dose intravenous gammaglobulin also implies "less chance" to develop coronary artery abnormalities.

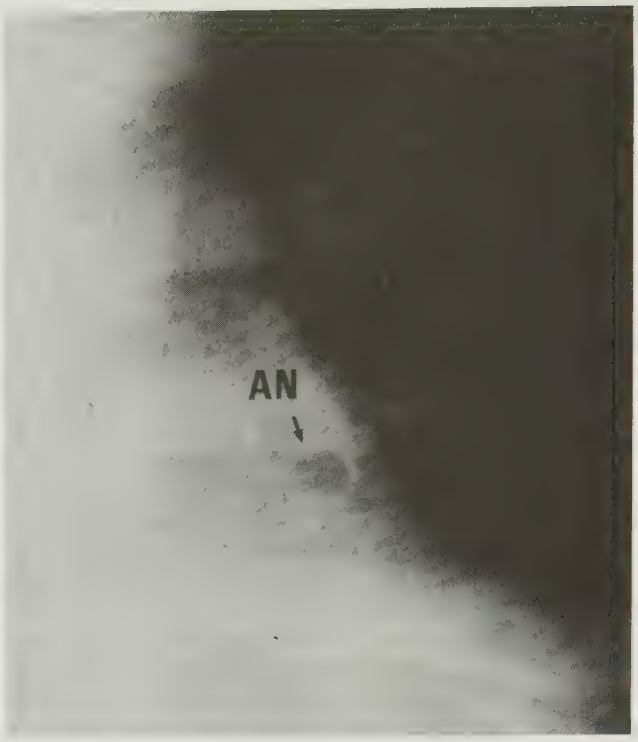

Fig. 89–14. PA view of a calcified left coronary artery aneurysm of a boy who had Kawasaki disease at 1 month of age. He had developed mitral regurgitation in the acute phase.

Modern technology represented by digital subtraction angiography (DSA), nuclear magnetic resonance imaging (NMR), and computed tomography may take place of selective coronary angiography and enable us to evaluate these patients noninvasively and safely.

Until further data become available, all individuals with a history of Kawasaki disease should be followed at certain intervals regardless of cardiovascular abnormalities.

CHAPTER 90

Infective Endocarditis

Richard A Friedman
Jeffrey R Starke

Infective endocarditis (IE) refers to a condition in which an organism or organisms infect the endocardium, the valves, or related structures. Previous injury to these structures by surgery, trauma, or disease usually has occurred. The infecting organism may be bacterial, fungal, chlamydial, rickettsial, or viral. In the first half of the twentieth century, a large percentage of patients with IE had prior rheumatic heart disease.[1] More recently, the majority of children with IE have complex congenital heart defects. Previous classifications divided cases between acute bacterial endocarditis (rapid, fulminant course with death occurring within 6 weeks) and subacute bacterial endocarditis (slow, indolent course, usually of several months' duration). The acute form usually was caused by Staphylococcus aureus, Streptococcus pyogenes, or Strep. pneumoniae, while the subacute form most commonly involved the viridans Streptococci. However, newer classification is based on microbiologic etiology rather than description, and the general term *infective endocarditis* is the more widely accepted term today.

EPIDEMIOLOGY

There is a wide disparity reported in the literature in the incidence of infective endocarditis in children. Most large series are retrospective and do not report the total number of admissions to that institution during the study period. During the decade 1952–1962, Zakrzewski and Keith[2] reported an incidence of infective endocarditis of 1 in 4500 pediatric admissions to the Hospital for Sick Children in Toronto. Johnson et al.[3] reported that 1 in 1800 admissions to Boston Children's Hospital during 1963–1972 were endocarditis, but that during 1933–1963 the incidence was only 1 in 4500. Finally, during 1972–1982, 1 in 1280 pediatric admissions to Case Western Reserve–Rainbow Babies Hospital was for endocarditis.[4]

The mean age of children with endocarditis is rising, almost certainly due to increased longevity following corrective or palliative surgery. Between 1930 and 1950 the average age was approximately 5 years,[5] but between 1960 and 1980 this increased to 8.5 to 13 years.[3,5,6] However, a large retrospective study comparing operated and unoperated children with congestive heart disease (CHD) who developed IE demonstrated no difference in the mean age of these groups of patients.[7]

A rapid rise has occurred in the incidence of IE in neonates without congenital heart defects. This increase seems to be associated with advances in life support in this population and the frequent use of indwelling catheters for nutritional and/or pharmacologic support.[8–12]

Virtually any congenital defect, including secundum atrial septal defect,[13–15] may predispose a child to the development of infective endocarditis. For example, Shah et al.[16] determined that the lifetime risk of developing IE in a patient with an unrepaired, simple ventricular septal defect (VSD) was 12 to 13%, while Steeg et al.[17] found that the risk was 3.2% over the first decade of life. In a large cooperative study on the natural history of aortic stenosis, pulmonic stenosis, and VSD, Gersony and Hayes[18] reported a risk of 9.7% of patients with unoperated VSD developing IE by age 30 years. However, if the patient underwent surgical repair, the incidence of IE was much lower. In contrast, the risk for patients with aortic stenosis (AS) (1.4%) was slightly increased after sur-

gical intervention; while patients with pulmonic stenosis had a 0.9% risk of developing IE.

In another study of 266 children, tetralogy of Fallot accounted for the largest percentage of patients with CHD who developed IE.[19] Similar findings are reported in other series from South Africa,[20] New York City,[21] and France.[22] Ventricular septal defect was the second most common lesion, accounting for 16% of the group, followed by AS (8%), patent ductus arteriosus (7%), and transposition of the great vessels (4%). However, other studies report that VSD[23,24] or aortic valve disease[25] (bicuspid aortic valve, aortic stenosis) were more common predisposing lesions. The most common lesions found in patients with CHD who developed endocarditis after surgery were tetralogy of Fallot (repaired with a systemic-pulmonary shunt) and transposition of the great vessels with pulmonary stenosis (repaired with a systemic-pulmonary shunt).[26] Several other patients had complex cyanotic CHD with shunts. Seventy percent of this group developed IE late (1 to >5 years) after their surgery. Similarly, in patients requiring prosthetic valves, 79% developed their infections more than 3 months after surgery. Predisposing events inducing a bacteremic state were identified in about one third of these cases. Details concerning the unoperated patients with underlying heart disease in this study are not well described but it appears the majority had either congenital valve deformities or valve disease secondary to rheumatic fever.

A smaller series from Yale–New Haven Hospitals found a higher incidence of IE in patients with CHD who had not undergone surgery than in those who had to be operated on.[6] Acyanotic lesions were more common in the unoperated group, while cyanotic lesions predominated in the postoperative group. Dacron patches and Gore-Tex grafts were more common sites of infection than prosthetic valves.

It appears that patients with "complete correction" of tetralogy of Fallot have a very low incidence of endocarditis compared with those patients who remain palliated. In a large series of 106 patients operated on from 1954–1960 and followed for a mean of 23.7 years, only one patient (1%) developed IE and no residual defects were noted in that patient at postoperative catheterization.[27]

Tricuspid atresia with diminished pulmonary artery flow is commonly palliated with a shunt procedure, usually a Waterston or classic Blalock–Taussig shunt. Patients receiving a classic Blalock–Taussig shunt may have an incidence of IE approaching 25%,[28] although a more recent series from Boston notes an incidence of 17%.[29]

Infective endocarditis associated with prosthetic materials, especially valves and valved conduits, is likely to increase in the future.[6,30] Prosthetic valve endocarditis (PVE) has been categorized as early (within 3 months of implant) or late onset. The incidence of infection ranges from less than 1% to 10% following implantation,[31–38] with a lower incidence being noted in the more recent series. Neither the type of valve nor the site of implant significantly affects the incidence of PVE.[38] Staphylococcus sp. predominate in early PVE, while Streptococcus sp. are the most common cause of infection in late-onset disease.[32–38] This pattern is probably a reflection of intraoperative contamination. The overall incidence of early PVE has been greatly reduced since the standard administration of perioperative antibiotics was instituted.

PATHOPHYSIOLOGY

Experimental animal models as well as clinical and autopsy investigations have shown that a series of events creates an environment suitable for the establishment of IE. Hemodynamic factors that predispose to turbulent blood flow and subsequent endothelial damage have been long studied. Lepeschkin[39] demonstrated involvement of the mitral valve in 86%, aortic valves in 55%, and tricuspid valves in almost 20% of 1024 autopsy specimens from patients with IE. He claimed that mechanical stress was a critical factor in the development of these valvular lesions. Rodbard[40] showed that a Venturi effect was responsible for the observation that the highest yield of bacteria would be found on the low-pressure sink side of a high-pressure jet (left atrial surface of mitral valve in mitral regurgitation, right ventricular side in VSD). The absence of large pressure differences in most cases of large secundum-type atrial septal defects probably explains the rarity of IE in this lesion, as opposed to small VSDs, which have high gradients. Turbulent blood flow damages the endothelium and initiates the formation of platelet and fibrin deposition. This series of events is similar to that seen in the course of primary plug formation with vascular injury.[41] Exposure to cold, high cardiac output states, hormonal manipulations, exposure to high altitudes, and passage of a sterile catheter across a heart valve also have caused initiation of this lesion in animals. Growth of the fibrin and platelet deposition results in the formation of a nonbacterial thrombotic vegetation (NBTV), which is essential in the pathogenesis of endocarditis. Transient bacteremias that occur as a normal part of daily life may cause colonization of the NBTV. As the NBTV grows and adherence of bacteria occurs, an infected vegetation develops. Virulence of different bacteria may directly relate to their ability to adhere to these NBTV. In vitro studies of bacterial colony forming units (CFUs) to determine an "adherence ratio" (cfu bacteria/cfu inoculum) have demonstrated that organisms most likely to cause IE clinically (enterococci, viridans Streptococci, Staph. aureus) adhered to valvular endothelium more readily than organisms rarely responsible for IE.[42] Another factor that may be important in increased virulence is the ability of certain streptococci found in the oral cavity to produce dextran. In fact, more than 50% of the streptococci responsible for IE produce dextran, although the percentage of dextran-producing organisms found in the bloodstream after dental manipulation is far lower.[43] The amount of dextran produced by the bacterial strain also may correlate with virulence.[44] It is unclear how these experimental findings actually relate to disease in humans. Another substance that may be a receptor for certain organisms is fibronectin. This substance is found on the surface of NBTV in polyethylene catheter–induced IE. Organisms such as Staph. aureus, Candida albicans, Strep. sanguis, and Strep. faecalis adhere to fibronectin, while organisms rarely found to cause IE do not.[43]

Once an NBTV is colonized, the size of the vegetation grows by increasing numbers of bacteria as well as by further platelet-fibrin deposition. The colonized NBTV produces a constant bacteremia and reseeding of the circulating organisms onto the already enlarging vegetation. Kissane[45] described three zones in the vegetation: 1) necrotic endocardium; 2) a broad zone of bacteria, pyknotic nuclear debris, and fibrin; and 3) a thin surface coat of fibrin and leukocytes. Proliferation of bacteria in the protected middle zone is relatively unchecked as the normal host defense mechanisms are unable to penetrate into the vegetation and penetration of any circulating antimicrobial agent is diminished.[46] The internal environment of the middle zone of the NBTV is such that

bacterial metabolism is depressed, and thus the action of any antimicrobial that is present is attenuated.

Pathologic changes observed in the heart are secondary to local extension of the infection. Vegetations may be single or multiple and range in size from less than a millimeter to several centimeters. Large lesions may resemble tumors and result in hemodynamically significant stenosis. Certain organisms, including Candida sp., Haemophilus sp., and Staph. aureus, may produce friable lesions that can embolize. Ulceration of tissue, especially heart valves, may result in perforation and produce the onset of sudden congestive heart failure. Other complications include rupture of chordae tendineae, abscesses of the valve ring and fistula formation with the development of pericardial empyema and tamponade, aneurysms of the sinus of Valsalva or ventricle,[47] and myocardial infarction secondary to emboli.[48]

Distant organ involvement secondary to embolic events may occur. One necropsy review of endocarditis in children found the lungs to be the most common site of distant organ involvement.[21] The kidney was the most frequently involved organ on the systemic side of the circulation, with splenic and cerebral infarcts somewhat less common. In other studies, cerebral emboli have been found in 30% of cases of IE in adults and children, with subsequent infarction, abscess, mycotic aneurysm, subarachnoid hemorrhage, and acute hemiplegia of childhood.[49] Microemboli to the cerebral circulation may occur and cause a confused mental state, while strokes are usually secondary to emboli to the middle cerebral artery.[50] Aortic valve infection probably has the highest incidence of embolic complications.[50] The ability to visualize a vegetation by echocardiography, which implies that the vegetation is large, is also probably related to the risk of emboli events.[51,52]

Immunologic mechanisms play an important role in the pathogenesis and sequelae of subacute IE. Cell-mediated and humoral immunity both are active in this disease process. A hypergammaglobulinemic stage usually exists and is due to both polyclonal and antigen-specific B cell activation.[53] Part of the hypergammaglobulinemia is due to circulating rheumatoid factors (RF)[43]; levels of RF may decrease with successful therapy and increase with relapse of disease. Both antibody responses directed at the infecting organism and nonspecific responses have been demonstrated. It is possible that C3b, in conjunction with circulating immune complexes, may bind to the surface of B cells and initiate production of antibodies not primarily directed at the infecting organism. Circulating immune complexes are found with increased frequency in patients with longstanding illness, right-sided disease, hypocomplementemic states, and extravalvular manifestations.[54] Bayer et al.[55] studied 29 patients with culture-proven IE and found that nearly all had levels of circulating immune complexes >12 μg/mL. A mixed-type cryoglobulinemia was noted in 90% of patients with IE.[56] Renal involvement with both focal and diffuse glomerulonephritis has been described and immune complex deposition is found in both conditions.[57–61] In addition, other autoantibodies, including antiendocardial, antisarcolemmal, antimyolemmal, and antinuclear antibodies, are found during the course of IE.[62]

CLINICAL MANIFESTATIONS

The clinical manifestations of IE are highly variable and depend on the underlying pathophysiologic disease processes. The extent of local involvement of the myocardium or valves, embolization from vegetations, and activation of immunologic mechanisms all play essential roles in clinical expression. Patients with acute IE may present in shock and with a clinical picture consistent with overwhelming sepsis. In some cases, confirmation of endocarditis may be found only during autopsy. In the subacute form of the disease, an indolent course may be seen with a diagnosis not established for weeks or months. Since endocarditis frequently occurs in children with underlying heart disease, subtle changes in their physical examination may be missed unless a high degree of suspicion is present on the part of the examiner. Table 90–1 lists the major clinical manifestations of infective endocarditis and their relative frequencies in children.

The most common finding with IE is fever, although it may be absent in up to 10% of cases. It is usually low grade and shows no specific pattern, especially in the subacute form. Other nonspecific complaints including malaise, anorexia, weight loss, fatigue, and sleep disturbances may be present. Involvement of the large joints, with arthralgias or arthritis, occurs in 24% of patients. Nausea, vomiting, and nonspecific abdominal pains are found in 16% of cases. Chest pains, which usually are related to myalgias but are sometimes secondary to pulmonary embolism, especially with tricuspid valve involvement, occur in up to 10% of older children.

The presence of heart murmurs in patients with infective endocarditis has been accepted as a "classic finding." In fact, murmurs usually are present in up to 90% of affected children. However, most of these patients have underlying congenital defects and initially presented with a murmur specific for their lesion. A new or changing murmur occurs in only 25% of children. Frequently, the absence of a changing murmur or the onset of a new murmur in children with pre-existing congenital lesions contributes to the delay in the diagnosis of IE. Congestive heart failure may occur in up to 30% of children and is especially common in those patients who develop a new murmur of valvular insufficiency.

Table 90–1. Symptoms and Physical Findings of Infective Endocarditis*

Symptom/Finding	*Frequency (%)*
Fever	56–100
Anorexia/weight loss	8–83
Malaise	40–79
Arthralgias	16–38
Gastrointestinal distress	9–36
Chest pain	5–20
Heart failure	9–47
Splenomegaly	36–67
Petechiae	10–50
Embolic events	14–50
New/changing murmur	9–44
Clubbing	2–42
Osler's nodes	7–8
Roth spots	0–6
Janeway lesions	0–10
Splinter hemorrhages	0–10

*Based on data from references 22, 39, 78, 94, 163, 171, and 179.

Exacerbation of congestive heart failure in children with rheumatic or congenital lesions who had been previously well controlled on chronic medical therapy should alert the clinician to consider the diagnosis of IE.

Signs and symptoms of neurologic involvement are seen in about 20% of children with IE. The sudden development of a clinical picture consistent with cerebral infarction in a child with an underlying heart defect should suggest the diagnosis. Acute hemiplegia, seizures, ataxia, aphasia, focal neurologic defects, sensory loss, and changing mental status may occur as a presenting feature or even years after the disease process has been treated.[63]

Splenomegaly occurs in about 55% of children with IE. It is usually found in patients with subacute disease and immune system activation. On palpation, the spleen is nontender. Hepatomegaly also is observed in many patients. Infarction of the spleen or abscess formation should be suspected in patients with left upper quadrant pain and tenderness that radiates to the shoulder area. A pleural friction rub or pleural effusion may be observed as well.

Specific skin lesions associated with IE are more common in adults than in children. Petechiae are seen in about a third of cases, especially in patients with a more chronic course. Common sites of involvement are the mucous membranes of the mouth, the conjunctivae, and the skin on the extremities. Petechiae are the most common skin manifestation in IE, occurring in up to 40% of patients; purpura has been reported but is rare.[43,64] Osler's nodes, which also have been described in systemic lupus erythematosus and in extremities distal to the sites of prolonged arterial catheterization, are exquisitely tender lesions. They are most commonly found on the pads of the fingers and toes, the thenar and hypothenar eminences, the sides of the fingers, and the skin on the lower part of the arm.[65] Much controversy still exists over whether Osler's nodes represent an immunologic response to infection manifesting as a vasculitis or whether they are septic emboli. Janeway lesions are differentiated from Osler's nodes in that they are nontender, hemorrhagic plaques that frequently occur on the palms and the soles and represent septic emboli with bacteria, neutrophils, and subsequent necrosis with subcutaneous hemorrhage.[66] Roth spots are small, pale, retinal lesions with areas of hemorrhage usually located near the optic disc. Osler's nodes, Janeway lesions, splinter hemorrhages, and Roth spots occur in only 5 to 7% of children with endocarditis.

Infants and neonates may present with a clinical picture less specific than that seen in older children. The onset is more acute and clinically mimics overwhelming sepsis. The diagnosis rarely is suspected prior to death.[67,68] Early reports concluded that endocarditis occurring in infants was not highly correlated to coexisting congenital heart disease.[69,70] However, more recent studies have concluded the opposite,[67] probably because of the earlier age at palliative or corrective surgery. The presence of indwelling vascular catheters has also increased the incidence of endocarditis in neonates. Persistent bacteremia associated with a deterioration in pulmonary function, coagulopathies, thrombocytopenia, and the appearance of murmurs should arouse suspicion of possible endocarditis in a neonate.

The clinical presentation of infective endocarditis in intravenous drug abusers has several distinctive features. Previous underlying heart disease is found in only one third of patients. The tricuspid valve is the most commonly affected site, and these patients often have pulmonary complications including infarction, abscess formation, and signs and symptoms of pleural effusions. Extracardiac sites of infection also are found in about two thirds of cases.[71] Tricuspid insufficiency with findings of a murmur of tricuspid regurgitation, a pulsatile liver, and gallop rhythm are found in 33% of patients.[72]

COURSE AND PROGNOSIS

The course and prognosis of patients with infective endocarditis is variable and depends on many underlying factors, including the severity of the primary cardiac lesion; the presence of prosthetic material; the infecting organism; the duration of illness prior to diagnosis and initiation of appropriate therapy; and the patient's clinical condition at the time of diagnosis (degree of respiratory, neurologic, and cardiovascular or renal compromise). Infective endocarditis was nearly 100% fatal in the preantibiotic era. At the present time, mortality is between 20 and 30%, due to improved methods of diagnosis and treatment with appropriate antibiotics. Mortality rates are somewhat higher in patients with acute staphylococcal infection, fungal infection, and prosthetic valve endocarditis. Sudden cardiac decompensation owing to congestive heart failure remains the single most important factor affecting mortality. Several studies in adults have directly correlated mortality to uncontrolled congestive heart failure. Mortality may be due to sudden perforation of the aortic valve with severe aortic insufficiency, chordal rupture with resultant mitral regurgitation, or myocardial necrosis with resultant intracardiac shunting through a ventricular or atrial septal defect or through a ventriculoatrial communication. Intramyocardial abscess formation with the development of myocarditis may be an important factor determining ultimate prognosis.[73]

Duration of therapy is dependent on the ability to eradicate the organism from the body. Surgical intervention is sometimes necessary, especially in prosthetic valve endocarditis or abscess formation.

Patients who survive will always be at risk for future development of IE by virtue of their underlying cardiac lesions or from residual damage as a result of their recent infection. Recurrence of disease after an apparently successful course of therapy may occur early (within 3 months of completion of therapy), or late (3 to 6 months after completion of therapy) and should be suspected if fever or other symptoms recur shortly after antibiotics are discontinued. The organism(s) found at relapse may be identical or occasionally different from the organism(s) identified initially.

LABORATORY INVESTIGATION

Table 90–2 summarizes the laboratory findings most commonly seen in children with IE. Blood cultures are the single most im-

Table 90–2. Laboratory Findings*

Finding	*Frequency (%)*
Elevated ESR	71–94
Positive rheumatoid factor	25–55
Anemia	19–79
Positive blood culture	68–98
Hematuria	28–47

*Based on data from references 22, 39, 78, 94, 163, 171, and 179.

portant diagnostic technique in establishing the diagnosis of IE. The wide spectrum of organisms that may be responsible for the infection dictates that scrupulous aseptic technique be utilized to assure that skin contaminants are not introduced into the blood sample. Bacteremia usually is continuous and low grade so that the timing and site of collection does not increase the yield.[74] In approximately 66% of all cases of IE, all blood cultures will grow the infecting organism[75]; in 90% of cases the first two blood cultures will be "positive." If a patient has received antibiotics prior to blood testing, the chance of obtaining a positive culture may be reduced from 95 to 100% to 64%.[22] When pretreatment has occurred, placing the blood sample into hypertonic media may enhance the chance of isolating the organism. Patients with fungal endocarditis may have only intermittently positive blood cultures. The organism may take one week or longer to grow in culture.[76]

Ideally, three to five sets of blood cultures should be obtained within the first 24 hours. These specimens should be obtained from different sites and contain from 3 to 5 mL of blood each. Thioglycollate broth should be used and the bottles kept for 3 weeks in order to detect slow-growing organisms. Nutritionally variant streptococci should be suspected if a Gram positive coccus is isolated in broth but fails to grow in subculture. The organism should then be subcultured onto media enriched with pyridoxal phosphate or L-cysteine.[77]

Blood cultures may be negative in 10 to 15% of cases of suspected endocarditis. Negative cultures may occur due to 1) prior administration of antibiotics; 2) endocarditis due to rickettsiae, chlamydiae, or viruses; 3) slow-growing (Candida sp., Haemophilus sp., Brucella sp.) organisms or nutritionally variant streptococci; 4) infections due to anaerobic organisms; 5) nonbacterial thrombotic vegetation endocarditis; 6) mural endocarditis; 7) right-sided endocarditis; 8) fungal endocarditis (esp. Aspergillus sp.); and 9) incorrect diagnosis.[78–80] Examination of the buffy-coat layer of peripheral blood may demonstrate the presence of bacteria within leukocytes. Additional sites including urine, sputum, cerebrospinal fluid, synovial fluid, bone marrow, and lymph nodes may be infected concomitantly. Thus, cultures of these additional sites may be included if blood cultures fail to demonstrate an infecting agent. Histologic examination of a surgical specimen, with proper staining techniques for bacteria and fungi, may also aid in diagnosis.

Adjunctive laboratory tests include the erythrocyte sedimentation rate (ESR), which is elevated in up to 90% of patients and correlates with the hypergammaglobulinemia found in this disease. An artifactually low ESR may be found with renal disease, severe congestive heart failure, or polycythemia. The ESR should decrease toward normal if therapy has been successful, and serial measurements may be helpful in monitoring therapy. A positive rheumatoid factor (RF) has been found in one fourth to one half of pediatric patients with IE and may be supportive evidence for the diagnosis when cultures are negative. Serial measurement of RF can be also used to monitor the adequacy of therapy in these patients.[81] Immune complex–mediated glomerulonephritis may result in hypocomplementemia. Anemia, usually due to a chronic disease state, is found in 40% of patients. Since children with cyanotic congenital heart disease frequently develop IE, the finding of a normal or slightly high hemoglobin level should raise the suspicion of anemia. Although leukocytosis is not uncommon, leukopenia may occur in acute cases with overwhelming sepsis. Microemboli and consequent microinfarcts in the kidney produce hematuria, with or without proteinuria, casts, and bacteremia, in 25 to 50% of cases.

Circulating immune complexes, as measured by either the Raji-cell radioimmunoassay[82] or ^{125}I-Clq binding assay,[83] are present in the majority of adults with IE, although they may be conspicuously absent in acute disease.[84] Immune complexes also may be found in septicemia and in up to 10% of normal adult controls. Several authors[55,85,86] have used the level of circulating immune complexes to differentiate endocarditis from septicemia and have used serial measurements to monitor therapeutic success. Levels of immune complexes >12 μg/mL occurred in 28 of 29 patients with culture-proven endocarditis.[55] However, one study of staphylococcal disease was unable to differentiate patients with endocarditis from bacteremic patients based on levels of immune complexes.[87] Though there have been few studies of circulating immune complex levels in children with IE, elevated levels have been found in some patients.[4,88]

Serologic testing for specific organisms may be helpful in culture-negative endocarditis. Antibodies against teichoic acids, which are major components of the cell wall in Staphylococcus aureus, may be present in 85% of adults with IE although the false-positive rate may be as high as 10%.[89–91] A teichoic acid antibody titer of $>1:1$ in a bacteremic adult patient correlates with deep-seeded infections including but not restricted to endocarditis. However, teichoic acid antibody levels do not differentiate the type of deep-seeded infection. As with circulating immune complexes, serial measurements of teichoic acid antibody levels may correlate with successful therapy. Unfortunately, no data exist concerning teichoic acid antibody levels in children with IE.

ECHOCARDIOGRAPHY

The role of echocardiography in helping to establish the diagnosis of IE has grown considerably because the technology has improved vastly since single crystal M-mode techniques were first introduced. Generally, the two-dimensional (2-D) technique is superior to the M-mode technique in the investigation for vegetative lesions. Some areas of the heart, such as the pulmonary valve, are better visualized using 2-D imaging, and the increased sensitivity of this technique with pulmonary valve endocarditis has been well documented.[92,93] The value of 2-D echocardiography in prosthetic valve endocarditis also is superior to that of M-mode. An echo-free space found in more than one tomographic plane has aided the diagnosis of perivalvular abscess[94] (which may complicate native valve endocarditis in up to 30% of cases, and more frequently in prosthetic valve endocarditis), and adjunctive use of Doppler technique to diagnose prosthetic valve regurgitation before it becomes clinically apparent may aid in earlier diagnosis. The sensitivity of echocardiography in detecting vegetative lesions in suspected endocarditis in adults ranges from 13 to 83%,[95,96] with the more recently published series utilizing 2-D technique exhibiting a greater sensitivity.

How the detection of echocardiographically proven vegetations correlates with morbidity and/or mortality is somewhat controversial. Some authors[97,98] have concluded that the detection of vegetations, especially if left-sided, may help to establish a subgroup of patients who would benefit by early surgical intervention.

Buda et al.[98] found vegetations on 21 of 50 (42%) adults with IE. Of interest is that most of the IV drug abusers with IE did not have detectable vegetations. They concluded that patients with a "positive echo" were twice as likely to develop serious complications, usually emboli, more commonly cerebral than peripheral, and that if the vegetation was >1 cm^2, patients were at higher risk for death or severe CHF, and more frequently required surgical intervention. However, the risk of embolization was not correlated with vegetation size. These findings are in accord with several other studies.[51,99–101]

In a study of 15 children with IE using both M-mode and 2-D technique, vegetations were detected in 10 of 15 (66%) of patients.[97] Of those 10 patients, three had systemic emboli and two died, while none of the patients without an echo-proven vegetation had an embolic complication. The authors suggested that echocardiography may help to identify a high-risk population that would benefit from surgical intervention. Some authors[102] have suggested that the size and mobility of a vegetation may be useful in differentiating bacterial from fungal endocarditis. However, in our experience, this claim is probably not valid inasmuch as large vegetations may frequently be seen in bacterial or fungal endocarditis.

On the other hand, a negative echocardiographic study does not rule out the presence of vegetations.[103] The resolution on most equipment limits the detection of vegetations to those greater than 2 to 3 mm in size. Poor technique also may hinder evaluation. Rheumatic heart disease with pre-existing valve disease, mitral valve prolapse with thickened leaflets, marantic vegetations, Loeffler's endocarditis, and Chiari networks in the right atrium and valve ring abscesses all pose interpretive problems to the echocardiographer.[104]

Once a vegetation is detected, it may show no significant change during therapy. Therefore, a recurrence of disease cannot be diagnosed unless a noticeable increase in size has occurred or a new vegetation appears.[104] Attempts to estimate serially the size of a vegetation are fraught with technical and interpretive error and probably of little value. However, continued growth of a vegetation coexistent with persistent bacteremia or evidence of further endocardial infiltration may indicate a treatment failure and/or the need for surgical intervention.[104–106] Examination of an echocardiogram at the time of hospital discharge of a patient after an apparently successful course of antibiotic therapy would be used as a baseline for that patient in further evaluation.

ELECTROCARDIOGRAPHY

Numerous electrocardiographic abnormalities may be found throughout the course of IE. Ventricular ectopy[107] in patients with hemodynamic compromise may be life-threatening. Atrial fibrillation has been reported[107,108] in both adults and children and may be secondary to atrioventricular valve regurgitation. Extension of abscess formation or the inflammatory response may cause direct injury to the conduction system. Complete right bundle branch block, left anterior or posterior fascicular block, and complete atrioventricular block have all been reported.[109] Abscess formation in the perivalvular aortic region may directly injure the atrioventricular node because of its close anatomic location to that structure. This may result in sudden death unless temporary and eventually permanent pacing is instituted.[110] One autopsy study of 125 patients with IE and cardiac abscess formation demonstrated conduction defects in 14 of 25 patients with nine deaths despite attempts at temporary pacing.[110]

PROPHYLAXIS

The use of antibiotics prior to and during any procedure that induces a transient bacteremia has become standard medical practice for the prevention of IE. However, the literature contains numerous reports of failures with subsequent development of endocarditis.[111] Although many times failure is related to inappropriate drug regimens, occasionally infection develops despite adherence to published guidelines. In an an attempt to consolidate current opinion on appropriate antibiotic regimens for endocarditis prophylaxis, the American Heart Association's Council on Cardiovascular Diseases in the Young Committee on Rheumatic Fever and Bacterial Endocarditis published recommendations in 1985 (Table 90–3).[112]

Numerous theories have been proposed to explain how antibiotics given prophylactically prevent endocarditis. Two possibilities are 1) that the antibiotic reduces the magnitude of a bacteremia associated with a procedure, and 2) that bacterial adherence mechanisms are altered such that a nidus of infection would be unlikely to develop. Hess et al.[113] examined the incidence of bacteremia after dental extraction in 82 children with cardiac disease who received penicillin prophylaxis. They found an incidence of 21%, half of which were streptococcal species. This compares with previous reports that noted a 0 to 53% incidence.[112] Interestingly, 6% of the isolated organisms were anaerobic. In addition, a number of penicillin-resistant organisms were found, although no child developed endocarditis. The authors hypothesized that although bacteremias still occurred, the microbial adherence was adversely affected by the antibiotics. This is supported by a recent rat model study that studied the effects of single-dose amoxicillin and erythromycin after the development of sterile aortic vegetations.[114] In this model, periodontally diseased teeth were extracted to produce a bacteremia similar to the conditions that might occur in human beings during dental manipulation. Endocarditis developed in 89% of the control group (vegetations but no prophylaxis). The organisms cultivated from the rat's dental plaque were identical to those found in blood culture, confirming the relationship between extraction and seeding of the vegetation. The incidence of bacteremia was nearly the same in the control group as in the treated group; however, essentially none of the treated group developed endocarditis. Another experiment, using rats with catheter-induced aortic vegetations, demonstrated a higher incidence of postextraction endocarditis in animals with periodontal disease as compared to those with healthy dentition. In this study, there was no correlation between the incidence of IE and the degree of bacteremia, suggesting that the rats with periodontal disease were at higher risk for other reasons not elucidated.[115]

Special circumstances arise concerning the use of antibiotic prophylaxis. Tables 90–4 and 90–5 list various conditions and procedures and the infecting organisms responsible for the development of IE in both children and adults. In patients requiring multiple dental procedures who have recently received antibiotic prophylaxis, oral streptococci with reduced susceptibility may flourish and possibly result in ineffective prophylaxis. Whereas giving 3 g of amoxicillin once per week does not result in a high

Table 90–3. Recommended Antibiotic Regimens for Endocarditis Prophylaxis in Children*

Regimen	*Condition*	*Dosage*
Dental/Respiratory Tract Procedures		
Standard	Dental procedures that cause gingival bleeding; oral or respiratory tract surgery	Penicillin V (1.0–2.0 g orally 1 hr before the procedure, then 0.5–1.0 g 6 hr later); for patients unable to take oral medications, 1–2 million units of aqueous penicillin G IV or IM 30–60 min before the procedure and 0.5–1.0 million units 6 hr later
Special	Parenteral regimen for use when maximal protection desired, i.e.: for patients with prosthetic valves	Ampicillin (50 mg/kg IM or IV) plus gentamicin (2.0 mg/kg IM or IV) one-half hour before the procedure, followed by 0.5–1.0 g oral penicillin V 6 hr later; alternatively, parenteral regimen may be repeated once 8 hr later
	Oral regimen for penicillin-allergic patients and those on rheumatic fever prophylaxis	Erythromycin (20 mg/kg orally 1 hr before the procedure, then 10 mg/kg 6 hr later)
	Parenteral regimen for penicillin-allergic patients and those on rheumatic fever prophylaxis	Vancomycin (15–20 mg/kg IV) 1 hr before the procedure; no followup dose is necessary
Gastrointestinal/Genitourinary Procedures		
Standard	Genitourinary/gastrointestinal tract procedures	Ampicillin (50 mg/kg IM or IV) plus gentamicin (2.0 mg/kg IM or IV) given 30 min to 1 hr before procedure; 1 follow-up dose may be given 8 hr later
Special	Oral regimen for minor or repetitive procedures in low-risk patients	Amoxicillin (50 mg/kg orally 1 hr before the procedure and 50 mg/kg 6 hr later)
	Penicillin-allergic patients	Vancomycin (15–20 mg/kg IV) plus gentamicin (2 mg/kg IM or IV) 1 hr before the procedure; may be repeated once 8 hr later

*From Shulman, S.T., et al.: Prevention of bacterial endocarditis: A statement for health professionals by the Committee on Rheumatic Fever and Bacterial Endocarditis of the Council on Cardiovascular Diseases in the Young of the American Heart Association. Am. J. Dis. Child., *139*:232, 1985.

incidence of resistant streptococci, erythromycin given at the same dosage may result in a significant number of resistant organisms.[116] Therefore, if prophylaxis is required twice in a month, amoxicillin can be given as recommended. In penicillin-allergic patients who require erythromycin, the interval between dental procedures should be increased if possible. If a dental abscess is found in a patient presently undergoing treatment for IE, it should be surgically drained.

Patients who develop a condition that must be surgically treated while being treated for IE should receive additional prophylaxis specific for the area of surgical interest and in accord with the published recommendations. It is also important to remember that patients receiving penicillin for rheumatic fever prophylaxis should receive additional prophylaxis as noted above.

Elective surgery, for whatever reason, should be postponed until treatment of active IE is completed. Other special circumstances that require prophylaxis include the presence of permanent transvenous pacing leads, cerebral ventriculoatrial shunts, and arteriovenous shunts.[112]

The use of antibiotic prophylaxis in patients with mitral valve prolapse (MVP) is controversial. This condition exists in approximately 5% of the U.S. population.[117,118] A case–control study comparing persons with MVP to normal controls found that the odds ratio for the association of IE with MVP was 8.2, and that it increased to 15.2 when a mitral regurgitation murmur was present.[119] Other studies have found similar risks.[120] A recent study attempted to define the absolute risk—the chance of developing IE over a time period—rather than the relative risk.[118] The group with MVP and no mitral regurgitation had an absolute risk for the development of IE of 0.0046% (one person in 21,950 persons per year) as compared to 0.520% (one person in 1920 per year) in the group with MVP and mitral regurgitation. Therefore, over a 50-year period, 26 of 1000 patients with MVP and mitral regurgitation would develop IE. However, only two of 1000 patients with MVP without mitral regurgitation would develop IE, which is not significantly greater than the risk to the general population. The authors of this study suggest that routine prophylaxis should be used only in patients with MVP and mitral regurgitation. This study also showed that male gender and age greater than 45 years were independent risk factors for the development of IE in patients with MVP, suggesting that they would receive added benefit from routine antibiotic prophylaxis.

Unfortunately, not many reports on the natural history of MVP in children address the risk of developing IE. None of the 30 children with MVP followed by Frand[121] for an average of 4 to 5 years developed IE, indicating no additional risk for this lesion. However, the relatively short duration of followup should preclude such a firm conclusion. Duren et al.[122] prospectively followed 300 patients with MVP with a mean followup of 6.1 years. They found a 6% incidence of IE, which accounted for 15% of all serious complications in these patients. Though the study design has been criticized,[123] including the lack of a control group, the mortality and morbidity that occurred in Duren et al.'s patients deserves

Table 90–4. Conditions and Procedures Related to Endocarditis Prophylaxis*

Cardiac Conditions for Which Endocarditis Prophylaxis Is Recommended
Prosthetic cardiac valves (mechanical and biosynthetic)
Most congenital cardiac malformations
Surgically constructed systemic–pulmonary shunts
Rheumatic and other acquired valvular disease
Idiopathic hypertrophic subaortic stenosis
History of bacterial endocarditis
Mitral valve prolapse with insufficiency
Foreign material in the heart
Cardiac Conditions for Which Endocarditis Prophylaxis Is Not Recommended
Isolated secundum atrial septal defect
Secundum atrial septal defect repaired without a patch 6 or more months earlier
Patent ductus arteriosus ligated and divided 6 or more months earlier
Procedures for Which Endocarditis Prophylaxis Is Recommended
All dental procedures likely to induce gingival bleeding
Tonsillectomy and/or adenoidectomy
Surgical procedures or biopsy involving respiratory mucosa
Bronchoscopy, especially with a rigid scope
Incision and drainage of infected tissue
Selected genitourinary and gastrointestinal procedures (cystoscopy, urethral catheterization, urinary tract surgery, gallbladder or colonic surgery, esophageal or anal dilatation, colonoscopy, upper GI tract endoscopy with biopsy, proctosigmoidoscopic biopsy)
Cardiac surgery
Procedures for Which Endocarditis Prophylaxis Is Not Routinely Recommended
Orotracheal intubation
Cardiac catheterization
Cesarean section
Therapeutic abortion
Intrauterine device insertion or removal

*From Shulman, S.T., et al.: Prevention of bacterial endocarditis: A statement for health professionals by the Committee on Rheumatic Fever and Bacterial Endocarditis of the Council on Cardiovascular Diseases in the Young of the American Heart Association. Am. J. Dis. Child., *139*:232, 1985.

serious consideration. Seven of the 18 patients in that study developed their infection after a dental procedure without prophylaxis.

The intermittent nature of the auscultatory click associated with some cases of MVP implies that the regurgitation associated with this lesion may be intermittent as well. Until further data concerning the exact incidence of mitral regurgitation associated with MVP in children is available, we believe that the safest course is to prescribe routine SBE prophylaxis for all children who have documented MVP.

MICROBIOLOGY

Many different organisms have been associated with IE in human beings. Table 90–6 lists the most common causative agents responsible for the development of IE. Gram-positive cocci are the causative agents in 90% of cases in which an organism is isolated. Streptococci, especially of the viridans group, remain the bacteria isolated most frequently. However, due to the increasing role of surgery and prosthetic material in the correction and palliation of congenital heart disease, the percentage of cases caused by staphylococci, Gram-negative bacilli, and fungi has increased.[3,68,124] Identification of the causative agent is the single most important procedure to confirm the diagnosis, direct therapy, and predict outcome and possible complications.

Streptococci

Streptococci are a heterogeneous group of organisms. There are different systems of classification that depend on several features, including patterns of hemolysis observed in blood agar plates, biochemical reactions, growth characteristics, antigenic reaction, and serologic relatedness. The least discriminating system uses the type of hemolysis produced by a strain of streptococcus when grown on a blood agar plate: beta hemolysis is a clear zone surrounding each colony caused by complete blood cell lysis; gamma hemolysis designates no detectable hemolysis; and alpha hemolysis is an inner layer of unhemolyzed cells and an outer layer of hemolyzed cells that produce a greenish discoloration in the medium. The term "viridans" streptococci refers to the majority of strains that are alpha hemolytic, although other strains such as the pneumococcus also may be alpha hemolytic. The group viridans streptococci is made up of many different species with varied biochemical properties and biologic behaviors. For instance, the viridans streptococcus, Strep. milleri, is especially virulent and causes a high incidence of suppurative intracardiac and extracardiac complications in patients with endocarditis.[125,126] When a viridans streptococcus is isolated from a patient with endocarditis, it may be valuable for the laboratory to perform species determination. The most common viridans streptococci isolated from adults with infective endocarditis are Strep. sanguis, Strep. bovis, Strep. mutans, and Strep. mitior.[127]

The Lancefield typing system[128] was devised to differentiate beta hemolytic streptococci into serogroups by means of antigenic differences in cell wall carbohydrates. Certain alpha and gamma hemolytic strains also contain group-specific antigen, such as enterococci that contain Group D cell wall carbohydrates. Therefore, viridans streptococci may be Lancefield typeable or nontypeable.

The viridans streptococci are the most common causative agents in childhood IE, accounting for about 40% of cases. These organisms are part of the indigenous flora of the mouth and gastrointestinal tract. Any procedure, such as dental surgery or extraction, that disrupts the mucosal integrity in these areas predisposes the patient to bacteremia with viridans streptococci. These organisms commonly cause endocarditis in patients with underlying heart disease, but are less common as causes of postoperative infection. Although viridans streptococci usually are associated with a more indolent, subacute clinical presentation, they can cause acute, rapidly progressive disease.[129] Most strains of viridans streptococci are exquisitely susceptible to penicillin, although prior antibiotic administration may promote infection with resistant strains. Recurrences and treatment failures are rare, but may occur.[130]

Nutritionally variant viridans streptococci are being recognized increasingly as the causative agent of IE in children.[10,131,132] The organism will grow in broth, but will not grow in subculture unless L-cysteine or pyridoxine is added to the media. These organisms must be looked for in every case of "culture-negative" endocarditis.

The enterococcus is an unusual strain of streptococci because

Table 90–5. Procedures Associated with Bacteremia in Children and Adults*

Procedure	*Associated Organism*	*Positive Blood Cultures (%)*
Dental extraction	Streptococcus, Diphtheroids	30–65
Chewing gum, candy	Streptococcus, Staph. epidermidis	0–51
Brushing teeth	Streptococcus	0–26
Tonsillectomy	Streptococcus, Haemophilus, Diphtheroids	28–38
Bronchoscopy (rigid scope)	Streptococcus, Staph. epidermidis	15
Bronchoscopy (flexible scope)		0
Nasotracheal intubation/suctioning	Streptococcus, aerobic Gram-negative rods	16
Orotracheal intubation		0
Sigmoidoscopy/colonoscopy	Enterococcus, aerobic Gram-negative rods	0–9.5
Upper GI endoscopy	Streptococcus, Neisseria, Staph. epidermidis, Diphtheroids, other	8–12
Percutaneous liver biopsy	Pneumococcus, aerobic Gram-negative rods, Staph. aureus, other	3–14
Urethral catheterization	Not stated	8
Manipulation of Staph. aureus suppurative foci		54

*From Everett, E.D., and Hirschmann, J.U.: Transient bacteremia and endocarditis prophylaxis: A review. Medicine, *56*:61, 1977.

it is much less susceptible to penicillin; successful treatment requires use of an additional antibiotic, usually gentamicin in children. Enterococcal endocarditis is less common in children than adults, accounting for only 4% of pediatric cases.[133] This strain inhabits the gastrointestinal and genitourinary tracts and may enter the bloodstream after instrumentation to these areas. While 40% of adult patients with enterococcal endocarditis have no underlying heart disease,[72] affected children rarely have previously normal hearts. Endocarditis should be considered in all infants and children with unexplained enterococcal bacteremia.

The pneumococcus is an alpha hemolytic streptococcus, but the clinical presentation of pneumococcal endocarditis is usually different from endocarditis carried by viridans streptococci. In the preantibiotic era, the pneumococcus accounted for 10 to 15% of cases of endocarditis, but now causes less than 2%.[134] Pneumococcal endocarditis may have a predilection for the mitral valve.[135] Approximately one half of cases of pneumococcal endocarditis occur in persons without underlying heart disease.[136] The clinical course usually is acute and fulminant, with valvular dysfunction and cardiac decompensation occurring frequently. Early surgical intervention usually is required, since the mortality rate with medical management alone is 75%.[134]

Endocarditis caused by β-hemolytic streptococci also was more common in the preantibiotic era than today. The majority of cases are due to Lancefield groups B and G strains,[137,138] whereas group C and A strains rarely cause endocarditis.[139,140] Group B streptococcal endocarditis may lead to large, bulky vegetations and arterial thrombi, which may be easily detected by echocardiography.[141] Noncardiac underlying conditions may include diabetes mellitus, pregnancy, intravenous drug abuse, genitourinary disease, and alcoholism. Mortality may approach 50%.

Table 90–6. Causative Agents in Pediatric Infective Endocarditis*

Organism	*Frequency (%)*
Streptococci	
Viridans	17–72
Enterococci	0–12
Pneumococci	0–21
β-hemolytic	0–8
Staphylococci	
Staph. aureus	5–40
Staph. epidermidis	0–15
Gram-negative aerobic bacilli	0–15
Fungi	0–12
Miscellaneous	0–10
Culture negative	2–32

*Based on data from references 22, 28, 39, 76–78, 94, 114, 163, 171, 179, and 195.

Staphylococci

Staphylococci are responsible for 20 to 30% of cases of IE in children, and the incidence is rising. The majority are due to coagulase-positive Staph. aureus, but coagulase-negative staphylococci are causing an increased number of post–cardiac surgery infections. Staph. aureus may attack previously normal heart valves as well as normal cardiac structures. It is the most likely cause of acute endocarditis in a previously normal child. The course is often fulminant, with frequent suppurative complications both in the heart (myocardial abscess, pericarditis, valve ring abscess) and in other organs.[142] Staph. aureus causes more than 50% of cases of endocarditis in intravenous drug abusers,[124] but the disease in this group of patients tends to be less severe than endocarditis due to other bacterial organisms.[143] The origin of the infecting strain is thought to be the addict's own nose or skin, not the injection paraphernalia.[144] Endocarditis associated with indwelling vascular catheters or prosthetic heart valves frequently is caused by Staph. aureus bacteremia, even if a peripheral focus of infection is present.[145] Treatment of Staph. aureus endocarditis has been complicated by the recent emergence of methicillin-

resistant strains, which may require synergistic antibiotic combinations, such as vancomycin and rifampin, for cure.[146]

The incidence of endocarditis caused by coagulase-negative staphylococci, usually Staph. epidermidis, also is rising rapidly. These organisms rarely cause infective endocarditis in persons without underlying heart disease, but are common causative agents of endocarditis following cardiac surgery.[147,148] Coagulase-negative staphylococci are the major responsible agents in prosthetic valve endocarditis, causing 25 to 67% of early cases and 25 to 33% of late cases.[31,149,150] These organisms can be locally invasive. The mortality rate of Staph. epidermidis prosthetic valve endocarditis with no valve replacement may approach 75% in adults.

Gram-Negative Organisms

Gram-negative bacteria are responsible for 4 to 5% of pediatric cases of endocarditis. However, the percentage of children with Gram-negative bacteremia who develop endocarditis is low. Burn patients, immunosuppressed hosts, recipients of prosthetic heart valves, and narcotic addicts are at increased risk for Gram-negative enteric bacteremia.[151,152] Many species of Gram-negative enteric organisms have caused infective endocarditis in children, but no clear pattern has emerged since data are limited to case reports and general medicine reviews. Morbidity and mortality are high, with frequent development of large vegetations, embolic complications, and cardiac decompensation. Endocarditis should be suspected in any patient with Gram-negative infection when bacteremia persists despite appropriate antibiotic therapy, especially if an unexplained heart murmur and anemia develop. However, in the early postoperative period after cardiac surgery, sustained Gram-negative bacteremia commonly is secondary to other foci of infection (i.e., urinary tract) and does not imply the presence of endocarditis.[153]

Pseudomonas sp. endocarditis is especially difficult to treat, with a high mortality rate.[154] Most patients with this type of endocarditis abuse intravenous drugs.[155] Major embolic complications and congestive heart failure are common.

Other Gram-negative organisms associated with infective endocarditis are the so-called HACEK Coccobacilli: Haemophilus sp., Actinobacillus sp., Cardiobacterium sp., Eikenella sp., and Kingella sp. This group caused 57% of cases of Gram-negative endocarditis seen at the Mayo Clinic from 1958 to 1979.[156] Endocarditis due to Haemophilus influenzae has been reported in several children,[157,158] but infections due to H. aphrophilus and H. parainfluenzae are more common.[159–162] A similar organism, *Streptobacillus moniliformis,* also has been linked to endocarditis.[163] Infective endocarditis in children due to other organisms of the HACEK group is extremely rare.[164,165] The infection usually occurs in the setting of pre-existing valvular disease and runs a subacute course. Embolic phenomena and central nervous system complications are common.[160] All HACEK organisms are fastidious, and may require 2 to 3 weeks for primary isolation, needing subculture onto chocolate agar in 5 to 10% CO_2 for optimal growth. These organisms should be considered in all presentations of "culture-negative" endocarditis.

In the preantibiotic era, Neisseria gonorrhoeae was responsible for 10% of cases of infective endocarditis. However, less than 40 cases have been reported since 1942.[166] The onset usually is acute. It tends to attack previously normal valves, valve replacement is frequently necessary. Nonpathogenic Neisseria sp. are isolated more frequently in endocarditis than gonococci, but these organisms usually attack abnormal or prosthetic valves.[167–169]

Gram-Positive Bacilli

Corynebacterium sp. are unusual causative agents of infective endocarditis, but may occur on either normal or abnormal heart valves.[170] Both toxigenic and nontoxigenic strains of C. diphtheriae can cause endocarditis in children.[171–173] Listeria monocytogenes endocarditis is rare in children and has a high mortality. However, unlike other forms of listeriosis, it is not seen frequently in immunocompromised hosts,[1] and has not been associated with listeriosis in neonates. Fewer than 30 cases of Lactobacillus sp. endocarditis have been described.[174] This infection usually follows dental manipulation in a person with underlying heart disease. Embolic phenomena are common, but treatment usually is successful if appropriate antibiotics are used.

Fungi

The most common predisposing conditions for fungal endocarditis in children are cardiovascular surgery, prolonged antibiotic usage, and the presence of an indwelling intravenous catheter. Most infections are caused by Candida albicans, but other species including, C. tropicalis, C. stellatoides, C. krusei, C. parapsilosis, and C. quilliermondi, have been implicated.[175] Endocarditis caused by intravenous drug abuse is more frequently caused by species other than C. albicans.[176] The clinical course usually is subacute. Embolic phenomena are extremely common and may be the first clinical indication of infection.[177] Large, friable vegetations occur frequently.[178] Ocular and cutaneous manifestations may aid in the diagnosis.[30] The prognosis of Candida sp. endocarditis is poor, related to the propensity for septic emboli to major organs, the tendency for invasion into the myocardium, and the poor penetration of antifungal agents into the vegetations. Diagnosis may be delayed by the tendency for negative or only intermittently positive blood cultures. Successful therapy usually requires surgical intervention.

Aspergillus sp. are the second most frequent cause of fungal endocarditis in children.[179,103] Most patients have had underlying heart disease and recent cardiac surgery, although normal valves can be affected.[180] The most frequent manifestations are fever and emboli, especially to the central nervous system.[181] Only four cases in children have been diagnosed antemortem, three by culture of peripheral emboli. Blood cultures usually are negative. Surgical removal of all infected material is recommended, although only one child has been treated successfully.

Other fungi that rarely cause infective endocarditis include Histoplasma capsulatum, Coccidioides immitis, Cryptococcus neoformans, Torlopsis glabrata, Hormodendrum sp., Mucor sp., Paecilomyces sp., Phialophora sp., and Chrysosporium sp.[182]

Other Organisms

Anaerobic bacilli cause 1% of cases of IE in adults.[183] However, reports of anaerobic endocarditis in children are exceedingly rare.[184]

Infective endocarditis caused by Coxiella burnetti (Q fever) has been documented in over 100 cases, including several children.[185] Clinical manifestations, including anemia, hepatosplenomegaly, fever and intracardiac vegetations, are similar in children and adults. Diagnosis is confirmed by serologic and immunohistologic

investigation. Although Q fever has been documented in the United States,[186] it is much more common in England, Australia, and France.

TREATMENT

Several general principles provide the basis of treatment of IE. The preferable route of antibiotic administration is intravenous. Oral antibiotics may be poorly or erratically absorbed, especially in infants, and often result in treatment failure. A course of at least 4 and up to 6 weeks or longer is required to sterilize vegetations and prevent relapse. Bacteriostatic agents are contraindicated and may lead to failure or relapse if used. Synergism between certain agents may produce a rapid bactericidal effect and allow smaller doses of each drug to be administered, thereby reducing possible toxic side effects. However, certain drug combinations, such as penicillin and chloramphenicol, may be antagonistic.

After initiation of therapy, daily blood cultures should be obtained. Although negative blood cultures do not necessarily correlate with a therapeutic success, continued positive blood cultures usually indicate the need to investigate the serum concentration of the drug in the patient, to add another agent, or to change therapy. If the patient has not responded clinically to initial antibiotic therapy within several days, additional blood cultures should be obtained. In addition, attention to the patient's clinical course is essential. Patients usually begin to improve within a few days of initiating appropriate therapy, although persistent fever may occasionally occur in patients with an eventual good outcome. Electrocardiographic monitoring should be performed in the early stages of therapy to assess the presence of arrhythmias or the development of conduction disturbances that may require immediate attention. If second-degree atrioventricular block develops during an episode of endocarditis, temporary transvenous pacing should be considered. Pacing should always be instituted for third-degree atrioventricular block. Physical examination to assess development of regurgitant murmurs or embolic events is also mandatory.

Current recommendations for optimal therapy in pediatric patients with IE are based largely on studies from adult patients. These regimens usually are more successful and less toxic in children than in adults (Table 90–7).

The timing of therapy generally depends on the patient's clinical condition. In a case of suspected IE in a seriously ill child, empiric therapy should begin immediately after obtaining the appropriate blood cultures. In patients in whom Staph. aureus infection is probable (acute presentation, IV drug abusers) a penicillinase-resistant penicillin should be added to the usual regimen of penicillin G and an aminoglycoside. The latter two agents would be employed in a patient with a subacute presentation and would be appropriate for viridans streptococci, enterococci, and most Gram-negative organisms. Patients who have recently undergone cardiac surgery should receive vancomycin in addition to an aminoglycoside because of the high incidence of hospital-acquired Staph. epidermidis, which may be resistant to methicillin or nafcillin. Once the blood cultures have been examined for sensitivity to various antibiotic agents, therapy may be appropriately tailored for the patient.

Several tests are available to determine how sensitive an organism is to treatment with antimicrobials. The minimal inhibitory concentration (MIC) is defined as the lowest concentration of the agent that prevents visible growth, usually in broth, after incubation for 18 to 24 hours. The minimal bactericidal concentration (MBC) is defined as the lowest concentration of the agent that results in either sterilization or a decline of bacterial count of 99.9 percent. Monitoring the inhibitory and bactericidal activity of the patient's serum is controversial. The Schlicter test is an in vitro determination of the maximal serum inhibitory and serum bactericidal levels specific for an infecting organism.[187] However, standardization of this test among different laboratories is poor, creating problems with interpretation.[188] Studies in rabbits with experimentally induced endocarditis show that bactericidal titers of 1:8 or greater usually correlate with therapeutic success.[189] However, in human beings with IE, no similar correlation was seen at titers of 1:8.[190] Although no formal recommendation exists, prospective studies[187] suggest that therapy should be tailored to achieve peak titers of 1:64 or greater and through titers equal to or greater than 1:32. The Kirby-Bauer disc sensitivity test is neither reliable nor quantitative and should not be used to guide therapy. Most viridans streptococci, Strep. pyogenes, Strep. pneumoniae, and nonenterococcal group D streptococci have an MIC for penicillin of less than 0.2 μg/mL in broth. Resistance, as defined by organisms with a MIC ≥0.2 μg/mL, occurs in about 15 to 20% of viridans streptococci. Tolerance occurs when growth of the organism is inhibited (a MIC to penicillin of less than 0.1 μg/mL) and the MBC is greater than eight times the MIC. Treatment failure may result when penicillin is used as the sole agent and organisms become tolerant to therapy.[191] Streptomycin and gentamicin each act synergistically with penicillin or vancomycin in vitro[61] and have been shown to be effective in eradicating vegetations in rabbits with experimentally induced endocarditis.[192]

In adults with IE caused by penicillin-sensitive viridans streptococci, an unacceptable relapse rate is obtained when penicillin is used alone for 2 weeks. However, when intramuscular procaine penicillin and streptomycin are given together for 2 weeks, 99% of patients are cured, a rate identical to a 4-week course of penicillin agents alone[193] or penicillin for 4 weeks with streptomycin administered concomitantly during the first 2 weeks.[194,195] The most cost effective and preferred therapy for uncomplicated penicillin-sensitive streptococcal endocarditis in young adults is the 2-week penicillin–streptomycin regimen.[72] Patients in renal failure or at risk for streptomycin-induced ototoxicity should receive 4 weeks of penicillin. In adults with a complicated course, prosthetic valve endocarditis, infections due to relatively penicillin-resistant organisms, or with symptoms for more than 3 months,[196] penicillin with the addition of streptomycin during the first 2 weeks is recommended. Gentamicin is preferred in pediatric patients because of its lower ototoxicity as compared with streptomycin. We reemphasize, however, that none of these regimens has been evaluated specifically in the pediatric population.

Most strains of enterococci have an MIC to penicillin ≥0.4 μg/mL and an MBC ≥6.25 μg/mL. Therefore, penicillin alone is ineffective and requires the addition of an aminoglycoside to act synergistically to effect a cure. Penicillin plus gentamicin is the preferred initial treatment because of a 20 to 50% resistance (MIC >2000 μg/mL) rate for streptomycin among enterococcal strains.[197] Streptomycin-resistant strains have been shown in vitro to respond to the synergistic effect of penicillin and gentamicin.[198]

Table 90–7. Recommended Antimicrobial Therapy for Infective Endocarditis in Children

Infecting Organism	*Antibiotic Agent*	*Alternate Agent in Allergic Patients*	*Length of Therapy (wks)*
Streptococci			
Susceptible viridans (MIC ≤0.2 μg/mL penicillin G)	Aqueous penicillin G[a] plus streptomycin[b] or gentamicin[c]	Vancomycin[d] plus/minus streptomycin[b] or gentamicin[c]	2–4
Resistant viridans (MIC ≤0.2 μg/mL penicillin G) and enterococci	Aqueous penicillin G[a] plus gentamicin[c]	Vancomycin[d] plus gentamicin[c]	4–6
Staphylococci			
Staph. aureus (methicillin-susceptible)	Nafcillin[e] or methicillin[f] with or without gentamicin[c]	Cephalothin[g] or vancomycin[d]	6–8
Staph. aureus (methicillin-resistant)	Vancomycin[d]	Same	6–8
Staph. epidermidis	Vancomycin[d] with or without rifampin[h]	Same	6–8
Gram-negative organisms			
Enteric bacilli	Ampicillin[i] plus gentamicin[c] (based on in vitro susceptibilities)		6–8
Pseudomonas aeruginosa	Ticarcillin[j] plus gentamicin[c]		6–8
Haemophilus	Ampicillin[i] with or without gentamicin[c]		4–6
Culture-negative			
Postoperative	Vancomycin[d] plus gentamicin[c]		6–8
Nonoperative	Nafcillin[e] or methicillin[f] plus gentamicin[c] with or without aqueous penicillin G[a]		6–8

All daily doses for children with normal renal function are as follows:
[a]Aqueous penicillin G: 200,000–250,000 U/kg, in divided doses q 4–6 hr.
[b]Streptomycin: 20–40 mg/kg, in divided doses q 12 hr.
[c]Gentamicin: 60–90 mg/m^2, in divided doses q 8 hr.
[d]Vancomycin: 40–60 mg/kg, in divided doses q 6 hr.
[e]Nafcillin: 100–200 mg/kg, in divided doses q 4–6 hr.
[f]Methicillin: 100–200 mg/kg, in divided doses q 4–6 hr.
[g]Cephalothin: 100 mg/kg, in divided doses q 6–8 hr.
[h]Rifampin: 15–30 mg/kg, in divided doses q 12 hr.
[i]Ampicillin: 200–300 mg/kg, in divided doses q 6 hr.
[j]Ticarcillin: 200–400 mg/kg, in divided doses q 6 hr.

Once susceptibility to streptomycin is determined, therapy can be adjusted accordingly and should be administered for 4 to 6 weeks.

In patients with IE due to Staph. aureus, a semisynthetic penicillinase-resistant penicillin is given for 6 weeks. Occasionally, a penicillin-susceptible strain (MIC <0.1 μg/mL) is encountered and penicillin G can be used. Although in vitro and animal model studies[199] have demonstrated enhanced killing of these organisms when gentamicin is added to nafcillin, no real value has been found in patients.[200] Therefore, this combination usually is reserved for seriously ill patients. Vancomycin is used in patients allergic to penicillin or in cases where methicillin resistance is encountered.[195] In addition, vancomycin is used in patients with hospital acquired infection due to Staph. epidermidis because of the high rate of methicillin-resistant organisms found in this infection. Bactericidal activity may be increased by the addition of gentamicin or rifampin and is recommended in prosthetic valve endocarditis secondary to Staph. epidermidis.[200]

Infective endocarditis caused by Gram-negative organisms requires individualized therapy based on the findings of in vitro susceptibility testing. When Klebsiella or Pseudomonas is involved, 6 to 8 weeks of therapy with two or more agents may be necessary. In addition, surgical therapy (see below) is frequently necessary. Infections due to Haemophilus sp. usually respond to ampicillin given for 4 weeks, although the addition of an aminoglycoside may improve outcome.[160] Most anaerobes are sensitive to penicillin alone, but when resistant B. fragilis are found, treatment with metronidazole is recommended.

Fungal endocarditis presents the clinician with several difficult problems. The overall survival rate is only 20% and only rarely is medical therapy successful in eradicating the disease. As mentioned previously, delay in diagnosis is frequently encountered because of slow growth in blood culture media. Embolic events frequently are the first serious sign of fungal endocarditis, and may necessitate immediate surgical intervention.[201,202] The primary antifungal agent used is amphotericin B alone or in combination with 5-fluorocytosine. Amphotericin B is given at a dose of 0.5 to 1.0 mg/kg/day. Though usually less severe in children than in adults, toxic reactions may necessitate altering the usual regimen. Fevers, chills, phlebitis, anemia, nephrotoxicity, renal tubular acidosis, hypocalcemia, and thrombocytopenia are the most commonly reported toxic effects. Although the optimal dose of amphotericin B is unknown, total doses of 20 to 50 mg/kg usually are used. Adults should not receive more than 50 mg/day. Therapy usually lasts at least 8 weeks, and evidence of recurrence must be looked for over a long period of time since relapses have been observed up to 2 years after a suspected "cure."[203] Amphotericin B penetrates vegetations poorly and may not prevent continued growth of the fungal organism.[204] Reseeding of the vegetation from distant metastatic sites may occur, further complicating attempts at cure. Most authors agree that the combination of antifungal agents and surgery is the treatment of choice in fungal endocarditis.

In patients with "culture-negative" endocarditis, empiric therapy with two or more agents is employed for 6 weeks, during which time efforts to identify an organism continue. In a study of culture-negative endocarditis in 52 adult patients, survival was correlated with clinical response to the initial choice of antibiotics, with most deaths attributable to congestive heart failure or systemic embolic events.[83]

The use of surgical therapy has been a valuable adjunct to medical therapy of IE in certain circumstances.[205–208] Most studies of the role of surgery have involved adult patients, with the inclusion of some pediatric patients. In a review of 139 patients who underwent surgical therapy for the treatment of IE, the most common reason for referral was congestive heart failure alone or combined with other conditions (i.e., embolization or persistent infection).[209] Aortic valve involvement predominated over mitral valve disease. The early mortality was 25% and the late mortality (>30 days) was 8.6%. Only 1.6% of the patients had residual infection despite the fact that 10% had a positive valve culture at the time of surgery. Jung et al.[210] reviewed the use of early surgical treatment in left-sided disease. The commonest indication for intervention was severe congestive heart failure alone (84%) or combined with other factors (12%). Their early and late mortality rates were 30% and 7%, respectively.[210] They noted that the most significant factor affecting survival was severe cardiac failure, and they emphasize the importance of early intervention. In their cases of fungal endocarditis, recurrent emboli and persistent infection were more common than severe congestive heart failure as the indication for surgery. When considering aortic valve disease alone, unstable hemodynamics may be the primary reason to perform surgery.[211] Placement of a prosthetic valve during active infection seems to contradict classical surgical techniques. However, the incidence of recurrent infection when prosthetic valve replacement is performed in patients other than IV drug abusers is surprisingly low.[166,211] There seems to be no difference in the reinfection rate of bioprosthetic valves as compared with prosthetic valves.[183] Double valve replacement (aortic and mitral) also has been successfully performed when the infection has involved both structures.[183] Extravalvular aortic root infection can also be managed successfully with aortic valve replacement, either alone or with a Teflon patch attached.[166] A recent study by Nihoyannopoulos et al.[212] evaluated surgical therapy in 106 patients at the Hammersmith Hospital in London, England. There were 12 patients with congenital heart disease, including seven with VSD, two with PDA, one with TGA, and two with secundum ASD. The primary indications for intervention were 1) heart failure secondary to valve destruction; 2) removal of a newly leaking prosthetic valve; 3) persistent or recurrent infection; and 4) large left-sided mobile vegetations regardless of the occurrence of embolism. Overall, the patients with congenital heart disease had the lowest mortality. The authors attributed this to the primary involvement of the right side of the heart and the low incidence of embolic events. Mortality was dramatically lower in surgical therapy of prosthetic valve endocarditis than in native valve endocarditis (10% vs 32%). The authors concluded that surgery should be considered earlier 1) when medical treatment is failing, 2) when large mobile vegetations are noted on echocardiographic study, and 3) when fungal endocarditis is encountered. Operative intervention can be performed with good results even during active infection. Patients with infected endocardial pacemaker leads in whom antibiotic therapy fails to sterilize the blood probably need to have these leads replaced and temporary pacing instituted. Permanent pacing leads can be safely placed after successful therapy. Patients who have been successfully treated for endocarditis and who have prosthetic material in the heart should not receive chronic oral "suppressive therapy" in an attempt to prevent a relapse.

CHAPTER 91

Myocarditis

Richard A Friedman

Myocarditis is an "inflammation of the muscular walls of the heart."[1] In 1984 a group of pathologists meeting in Dallas attempted to define this rather broad term as "a process characterized by inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease."[2] This chapter discusses proven or presumed infectious causes for myocarditis and describes the clinical presentation and etiologies when known.

Myocarditis may be secondary to many of the common infectious illnesses that affect children and infants (Table 91–1), or it may occur as a manifestation of hypersentitivity or as a toxic reaction to drug administration. In general, myocarditis may go unrecognized in a large percentage of patients whose illness resolves spontaneously; in contrast, it may lead to fulminant disease with a rapid progressive downhill course or a chronic state possibly leading to dilated congestive cardiomyopathy.

Early descriptions in the first half of this century classified myocarditis as idiopathic, with histologic findings of diffuse or focal interstitial inflammation. The term *Fiedler myocarditis* has its origins in the description by Fiedler of pathologic changes found in adult patients. He described a diffuse or focal idiopathic or isolated interstitial myocarditis.[3] Myocarditis as a result of rheumatic fever, diphtheria, or other bacterial infection was well recognized although many experts suspected that viruses were also involved in the pathogenesis of the disease.[4]

Myocarditis is a relatively uncommon finding in children, representing only 0.3% of 14,322 patients seen in the cardiology service at Texas Children's Hospital between the years 1954 and 1977. This rate is similar to the findings of a group at the Toronto Children's Hospital between 1951 and 1964.[5] However, not all cases of myocarditis are recognized by the clinician and a much higher incidence is noted in autopsy series. During the same two decades, an autopsy incidence of 1.15% was found at Texas Children's Hospital. This is in contrast to the report by Saphir and colleagues[4] who noted an incidence of 6.83% among 1420 autopsies on children. In Saphir's series nearly one third of the cases were believed to have rheumatic carditis, though this finding was extremely rare in the series from Texas Children's Hospital using histologic examination of the heart (only two patients). One study attempted to estimate the evidence of myocarditis in children who had died suddenly.[6] The control group consisted of children who died a violent death with no history suggestive of myocarditis. They found that 17 of 138 cases (12.3%) revealed evidence of active or healing myocarditis. Fifteen of these cases occurred in the 90 children who died suddenly. In contrast, only 4.2% of 48 children dying a violent death had histologic evidence suggestive of myocarditis. Unfortunately, this was a retrospective study and viral cultures and serologic studies were not routinely obtained at autopsy. In addition, the two groups were not matched for age, sex, or time of death, which may have affected the interpretation. The authors suggested that although further study was needed, the incidence of "silent" myocarditis in children might be higher than expected.

An even greater discrepancy is found in the series by Burch and colleagues,[7] who found evidence of interstitial myocarditis in 29 of 50 infants and young children who underwent routine postmortem examination. Several investigators have found recently that a significant number of patients undergoing endomyocardial biopsy for unexplained myocardial dysfunction had histologic find-

ings suggestive of myocarditis.[8,9] Likewise, patients being investigated for occult ventricular arrhythmias for which no etiology could be proved have also been found to have evidence of interstitial lymphocytic infiltrates suggestive of myocarditis.[10,11] Pomerance and Davies[12] have pointed out the potential for overdiagnosis of myocarditis, noting that about 5% of "normal" hearts may be found to have minor foci of inflammatory cells. They determined that a normal finding was 25–30 interstitial lymphocytes per square millimeter. In addition, the number of lymphocytes per square millimeter in endomyocardial biopsy specimens was less than that found in autopsy specimens (3.5 versus 7.2 cells per square millimeter).

The discrepancy between clinical and autopsy series could be explained by the fact that in a significant number of cases of myocarditis the manifestations may be subclinical and recognized through other findings, such as ECG changes, or perhaps not at all. Myocarditis may also be only one component of a generalized disease; if the cardiac dysfunction is mild, it may be completely overlooked.

EPIDEMIOLOGY

Myocarditis is generally a sporadic disease, although epidemics have been reported. Coxsackievirus B has been the most frequently reported cause of epidemics in children. Geer and Measroch[13] were the first to identify this organism in association with myocarditis, during a nursery epidemic in southern Rhodesia. Other reports from Rhodesia,[14] Holland,[15] the United States,[16] Singapore,[17] and South Africa[18] followed. Infections secondary to coxsackieviruses are common throughout the general population. Target organs include the upper respiratory tract, the gastrointestinal tract, liver (hepatitis), lung (pneumonia), central nervous system (meningoencephalitis), lymph nodes (infectious mononucleosis–like syndrome), the kidney (hemolytic uremic syndrome), and the heart (carditis).[19–21] Significant titers of type-specific protective antibodies are present in most adults in the United States.[21] However, as hygienic and socioeconomic conditions improve, fewer children likely will become infected with this virus. Thus, the potential exists for a greater segment of the adult population to become susceptible to these viral agents later in life.[22] This may become an important problem in pregnant women who, if infected late in pregnancy, may transmit the virus to the fetus in utero or to the neonate. After birth, spread occurs by the fecal/oral or airborne route. The coxsackieviruses B use receptors that are not shared with other enteroviruses to attach to their target cells. It is these receptors that are believed to be essential for viral replication and

may help to determine tissue tropism.[23] Infections owing to the coxsackievirus B or enteroviruses are subclinical in 50% of cases.[21] During an outbreak of coxsackievirus B virus in Europe in 1965, cardiac manifestations were noted in 5% of patients.[24,25] That same year, in similar outbreaks of the disease in Scotland, Finland, and Austria, a much higher incidence of patients (12%) developed some evidence of myocardial dysfunction.[22,23] While myocarditis has been associated with coxsackievirus B serotypes 1–6, the most serious disease has been attributed to types 3 and 4.[16,20,26] Burch et al.[7] demonstrated coxsackievirus B antigens with the use of an immunofluorescent technique in 41% of 29 infants and children who had interstitial myocarditis at routine autopsy. Another study[27] found 1299 cases of unexpected death in an autopsy series of 2427 patients. These authors were able to identify 20 cases of viral myocarditis in this group. Of the 20, nearly half had positive serologic evidence of coxsackievirus B infection. Karjalainen et al.[28] found a 9% incidence of myocarditis in 67 verified cases of influenza infection during a 1978 epidemic in Sweden. Though much less common, coxsackievirus A and echoviruses have also been suspected of causing myocarditis.

Rubella virus, a teratogen during the first trimester of pregnancy, has been implicated in myocarditis. Persistence of the virus in the fetus has been shown to produce severe cases of myocarditis.[29] One study found 10 of 47 infants with congenital rubella to have evidence of myocarditis.[29] Seven of these infants had active disease, and four died with severe myocardial failure. Morbidity secondary to chronic cardiac dysfunction was felt to be severe in the survivors. A significant reduction in the number of cases of congenital rubella has occurred because of aggressive immunization programs, and only 28 cases of rubella myocarditis were recorded in 1975.[30]

Herpes simplex virus infects newborns at a rate of 1 per 7500 deliveries.[31] The types 2 virus is most common and is usually acquired from the mother's genital tract. The wide spectrum of this disease ranges from mild, clinically inapparent disease, to severe fatal encephalopathy. Herpesvirus has been found in the myocardium of autopsy specimens, thus documenting its association with myocarditis.[32]

Osama et al. found a 5.8% incidence of myocarditis in 312 cases of varicella during a one-year period.[33] Patients who complained of skeletal myalgia seemed to have a significantly higher risk of developing cardiac involvement.

PATHOLOGY

Immunology

The microscopic and immunologic changes seen in patients with viral myocarditis have been well described. However, to examine the immunopathogenesis of this disease, it has been necessary to use animal models, the most thoroughly studied of which has been the murine model. Coxsackievirus B and encephalomyocarditis viruses have been extensively studied.

It has been demonstrated that between 24 and 72 hours after infection with coxsackievirus B, a viremia exists, with maximum growth in the tissues between 72 and 96 hours.[34] Shortly thereafter, virus titers decline; essentially no organisms can be found by 7 to 10 days after inoculation.[23] As virus titers decline, antibody concentrations increase, implying that antibody has an active role in viral clearance.[35] Macrophages appear 5 to 10 days after infection in the coxsackievirus B model of myocarditis.[23,36]

Factors that have been shown to affect the severity of myocarditis in the murine model include age, strain of mouse, viral variant, and gender of the host.[37] Several mechanisms have been shown to be active in the production of myocarditis in this model. Viruses have been shown to be directly associated with myofiber destruction.[38–40] However, the greatest degree of damage is probably due to an interaction between the myofiber and T cells. Viral-induced changes of the myocardial cell produce a neoantigen that is recognized by cytotoxic T lymphocytes, which preferentially destroy the myocardial cell. In addition, coxsackievirus may induce cytotoxic T lymphocytes that are autoreactive against antigens on infected myocytes. Mice who are pretreated with antithymocyte serum and thus lack a normal immunologic response develop a less extensive myocardial necrosis when compared with animals similarly infected and treated with normal rabbit serum.[23] Animals who are deficient in T cells clear their viremia normally, but develop a significantly lesser degree of myocardial injury. The implication is that the T cells are not required in elimination of virus, but play a delayed role in the major inflammatory response.[23,40] Mice who are pretreated with neutralizing antibody fail to develop myocarditis,[32,41–43] which implies that a combination of macrophages and antibody suppresses viral infection.

Another type of cell—the natural killer (NK) cell—is important in the pathogenesis of myocarditis. Animals who are depleted of their NK cells prior to infection with coxsackievirus have been shown to develop a more severe myocarditis. One study[44] used murine skin fibroblasts to demonstrate the antiviral activity of activated NK cells. Natural killer cells are activated by interferon, which is an indirect modulator of myocardial injury. Murine skin fibroblasts served as target cells for coxsackievirus B–sensitized cytotoxic T cells. The NK cells were shown to specifically limit the nonenveloped virus infection by killing the virally infected cells. This finding has important implications in host immunity and may help to explain why female mice develop a less severe myocarditis than males. Male mice have been shown to be much less efficient in activating NK cells, which, as mentioned above, are directly responsible for viral clearance. Presumably, the more efficient viral clearance is, the less is the opportunity for viral-induced neoantigen production and recognition by cytotoxic T lymphocytes.

Woodruff has elucidated the different ways that T cells can effect injury.[23] They include accumulation of activated macrophages, production of antibody and antibody-dependent cell-mediated cytotoxicity, direct lysis by antibody and complement, and direct action of cytotoxic T cells. The primary importance of cytotoxic T cells in direct myocardial cell injury was demonstrated in BALB/c mice infected with coxsackievirus B3.[40] Both virus-infected and noninfected myocytes were destroyed in T cell–deficient animals. The infected host cells were thought to stimulate the production of a subset of cytotoxic T cells responsible for the injury. These cells then recognize virus-specific and major histocompatibility antigens (modified H_2 antigens) present on the cell surface and directly interact, resulting in myocytolysis. This ongoing injury has been considered an autoimmune-type process.[23,40] In support of this concept, Pacque et al.[45] infected the CD1 mouse with coxsackievirus B3 and demonstrated in the hearts of mice previosly infected with this virus a KCl extractable antigen

that was specifically immunoreactive with immune mouse peritoneal exudate cells (i.e., that stimulated production of a migration inhibitory factor). The authors were unable to demonstrate viral activity in animals who had this extractable antigen. In addition, antigen responsible for cytotoxic T-cell activity cannot be detected by using antiserum containing antibodies directed at the structural components of the viral capsid. The ineffectiveness of antiviral serum in preventing myocarditis has also been demonstrated.[46]

Lyden et al.[47] studied the susceptibility variation of the BALB/c mouse to coxsackievirus B3. The age of greatest susceptibility was between 16 and 18 weeks, with males having a maximal rate of myocarditis greater than that seen in females. Enhanced myocarditis seen in older females was eliminated when they were treated with estradiol, implying that sex hormones play a key role in host susceptibility. In vitro and in vivo studies have shown that testosterone seems to increase the cytolytic activity in males preferentially over females. Either a preferential stimulation of T helper cells or an inadequate stimulation of T cytolytic/suppressor cells could explain why antibody responses to various antigens may frequently be enhanced and cellular immune responses depressed in females. Huber and Lodge[48] demonstrated that host genetic composition not only affects the severity of disease, but also plays a role in the pathogenic mechanisms involved. Important differences were found when coxsackievirus B3 was used to induce myocarditis in the BALB/c mouse and the DBA/2 mouse. The BALB/c mouse developed myocarditis in response to cytolytic T cells. Two distinct cytolytic T cell populations are formed in the BALB/c mouse: one recognizing virus-infected cells and producing direct myocytolysis, and another that destroys uninfected myocytes and is believed to be an autoreactive lymphocyte. Complement depletion increased the amount of inflammation in this species, and no reactive immunoglobin G antibody was found in the myocytes. In contrast, in the DBA/2 mouse it was the T helper cells that indirectly mediated the course of disease, and complement depletion reduced inflammation in this species. Cytolytic T cells are produced, but apparently are not pathogenic and immunoglobin G antibody is found in the myocytes.

Several other viral agents have been used to produce experimental myocarditis. Sakamoto et al.[49] produced myocarditis using influenza A virus (H2 N2) in mice. Mice who were pretreated with radiation or depleted of T lymphocytes did not develop disease. Encephalomyocarditis virus (ECM) has been used to develop models of acute and chronic myocarditis in mice. This virus is a picornavirus, similar to the coxsackievirus group. Studies have demonstrated a progression from acute myocarditis to dilated cardiomyopathy similar to that seen in human beings.[41,50]

Several studies have been done in human beings as well. Maisch et al.[51] demonstrated antibody-mediated cytolysis in 30% of 144 patients with suspected myocarditis as well as in 18 of 19 patients with proven viral infections due to coxsackievirus B, influenza A, or mumps. A muscle-specific antimyolemmal antibody (AMLA) was found in these patients and correlated with the degree of in vitro induced cytolysis of rat cardiocytes. Bowles et al.[52] used complementary DNA (to coxsackievirus B2 RNA) cloning techniques and developed a coxsackievirus B–specific cDNA "hybridization probe" that detected virus nucleic acid sequences in patients diagnosed as having active or healed myocarditis or dilated cardiomyopathy. As a control they used patients with unrelated disorders and found no virus-specific sequences in those patients. This suggested that in patients with congestive cardiomyopathy or healing myocarditis, viral particles persist even though viral culture is almost always negative. The findings imply a continual viral replication in cells, which may conceal the antigenicity by an immunologic process that prevents correct posttranslational processing of capsid proteins.[52] Hori et al. found adult patients with myocarditis to have been exposed to a greater number of coxsackievirus B1–6, as demonstrated by the number of positive and negative responses to neutralizing antibodies of those viruses.[53] These authors believed that immunization against several types of coxsackievirus B was essential in the development of myocarditis. Although they postulated this "cross immunization" theory, a few cases of myocarditis in their patients involved exposure to only one type of coxsackievirus B, shedding doubt on the validity of their theories.

A defect in cell-mediated immunity as expressed in a reduction in concanavalin A–induced suppressor cell activity has been demonstrated in patients with myocarditis and dilated cardiomyopathy as compared with healthy controls.[54]

In summary, the pathogenesis of myocarditis can be viewed as follows (Fig. 91–1). Infection of the mouse with coxsackievirus B3 induces a viremia and replication of this virus within the myocardial cells. Direct viral myocytolysis ensues, with production in other cells of neoantigen in response to viral infection. Cytotoxic T cells directed at both infected and noninfected (autoimmune) cells produce further injury. Natural killer cells attack the virally infected cells only and are responsible for viral clearance. Antibody binding and complement-mediated cell destruction also occurs in the delayed immunologic response. Host factors, including age, sex, and immunocompetence, play key roles in modulating these processes.

Gross and Microscopic Findings

The pathologic findings are usually nonspecific, with similar gross and microscopic changes noted irrespective of the causative agent.[3,4,55–59] Grossly, the weight of the heart is increased; all four chambers are affected. The muscle appears flabby and pale with petechial hemorrhages often seen on the epicardial surfaces, especially in cases of coxsackievirus B infection. A bloody pericardial effusion may also be seen relating to the often combined finding of pericarditis. The ventricular wall is frequently thin, though hypertrophy may be found as well. Usually the valves and endocardium are not involved, although they may be glistening white in cases of chronic myocarditis. This finding has suggested to some investigators that the disease process known as endocardial fibroelastosis, which may present with similar clinical findings, could represent an end result of viral myocarditis, possibly induced in utero.[60,61] Hutchins and Vie[61] studied the hearts of 64 children with a diagnosis of myocarditis or endocardial fibroelastosis. They found that 41 patients had features shared by both diseases, 18 had endocardial fibroelastosis only, and 5 had myocarditis only. A history of acute illness (disease onset to death 2 weeks or less) was found only in the patients with myocarditis. In the 41 patients in whom features of both diseases existed, the time from onset of disease to death was between 2 weeks and 4 months, while in cases of endocardial fibroelastosis the onset of disease to death was greater than 4 months. Support for this observation was reported by Hastreiter and Miller,[60] who found microscopic evidence

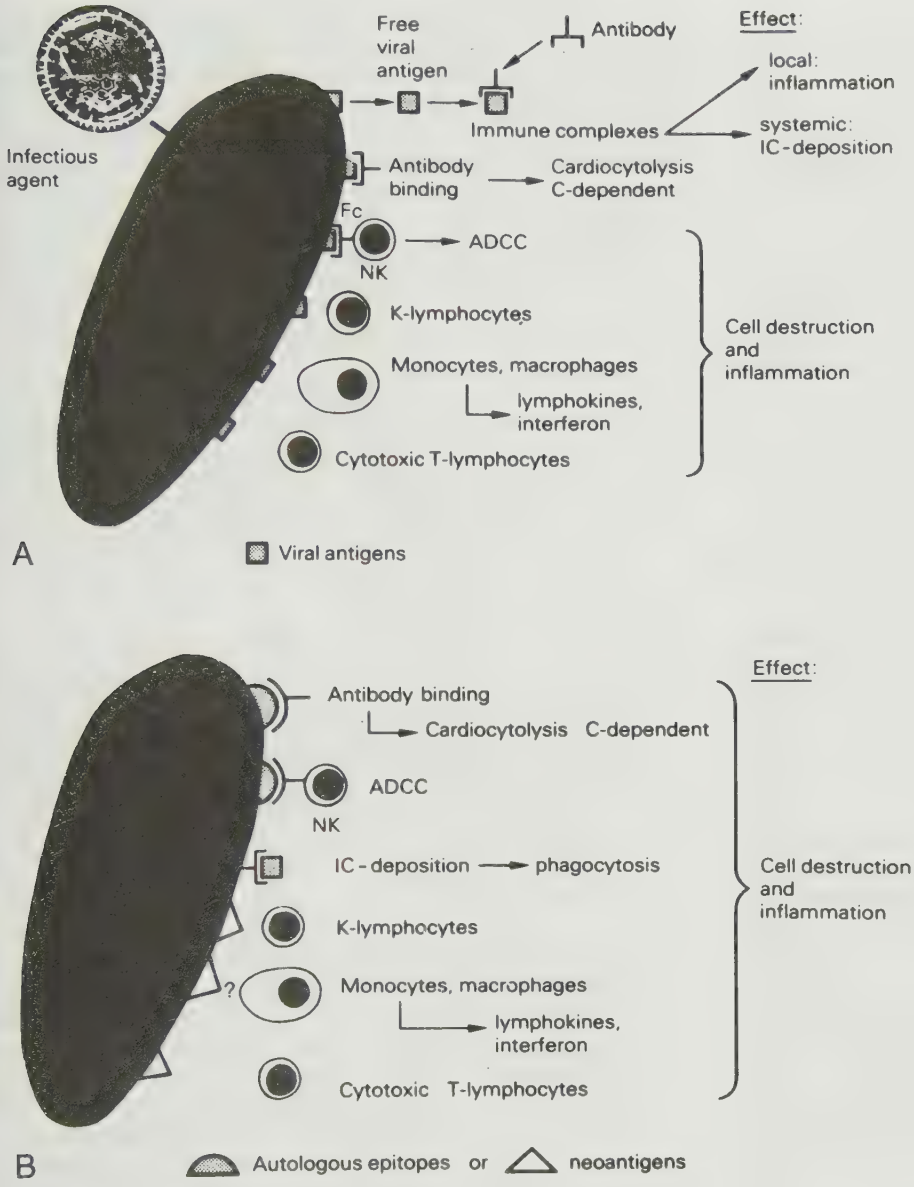

Fig. 91–1. (A) Early immunopathogeneis. The cell cycle is altered by viral infection. Viral proteins are expressed on the surface of the cell and become targets of various immunologic effectors. These include the monocytes and macrophages, which release mediators; cytotoxic T lymphocytes and K cells, which lyse the myocardial cell; and NK-cells, which together with antibodies also effect cell lysis. Complement-activated antibody-mediated cell destruction also occurs, with the production of antiviral antibodies. Formation of immune complexes may occur when circulating viral antigen is coupled to viral antibodies, resulting in local or systemic reactions. (B) Delayed immunopathogenesis. In addition to the mechanisms described in (A), modulation of the inflammatory response by T cells (helper and suppressor types) against autologous heart cells occurs. Complement-activated antibody-mediated cell destruction is more important than antibody-dependent cellular cytotoxicity (ADCC) in this phase of the injury process. The presence of viral antigens during this phase is negligible compared with the level present during the early phase of injury.

of myocarditis after transthoracic needle biopsy in a child who had the classical clinical picture of endocardial fibroelastosis.

Fruhling et al.[62] demonstrated coxsackievirus B3 in the myocardium of 13 of 28 infants with endocardial fibroelastosis, and Van Reken et al.[63] found echovirus 9 in a 5-month-old infant with myocarditis and severe congestive heart failure who also had histologic findings consistent with endocardial fibroelastosis. In addition to isolating virus in the heart and lungs, the liver and lymph nodes were also involved in the latter case.

Mural thrombi have been described in the left ventricles of some patients with myocarditis as well as small emboli in the coronary and cerebral vessels.[64] Coronary emboli, though rare, may produce areas of ischemia and/or injury with resultant production of the cardiac arrhythmias that sometimes occur during the acute disease.

The typical microscopic picture of acute myocarditis is that of a focal or diffuse interstitial collection of mononuclear cells, including lymphocytes, plasma cells, and eosinophils. Polymorphonuclear types are only rarely noted, except in cases of bacterial myocarditis. As mentioned previously, viral particles are rarely recognized on electronmicroscopic investigations.[59,65]

Extensive necrosis of the myocardium, with loss of cross striation in the muscle fibers and edema, is seen in severe infections, but especially with coxsackievirus. Perivascular accumulation of lymphocytes and plasma cells has been described with coxsackievirus B myocarditis but is usually a minor finding. In disease due to rickettsiae,[56] varicella,[66,67] trypanosomes,[68,69] or other parasites,[70] and in reactions to sulfonamides,[71] this is a much more prominent finding.

Myocarditis secondary to diphtheria infection is frequently complicated by arrhythmias, especially complete atrioventricular block. Diphtheria exotoxin has a particular affinity for conductive tissue. It interferes with protein synthesis by inhibiting a translocating enzyme in the delivery of amino acids. Triglyceride accumulation occurs as a result of induction of abnormal carnitine metabolism, and fatty changes of the myofibers are seen.[72]

Myocarditis due to bacterial agents usually presents a different

picture than that seen with disease due to viral agents. Microabscesses and patchy focal suppurative changes may be seen.[72] A combined perimyocarditis is also frequently encountered.

Trichinella species usually cause a focal infiltrate with lymphocytes and eosinophils. Larvae are usually not identified.

A severe myocarditis may develop in response to Trypanosoma cruzi, with the development of Chagas' disease. This disease, which is uncommon in North America, can affect up to 50% of the population in an endemic region, such as South America. Protracted heart failure and death may ensue after acute infection. Microscopic examination demonstrates the presence of the organism as well as neutrophils, lymphocytes, macrophages, and eosinophils.[72]

Sudden infant death syndrome occurs in up to 1 in 500 children and could be due to cardiac arrhythmias that may result from myocardial inflammation.[73] James[74] described a resorptive, degenerative process in the His bundle and left margin of the atrioventricular node with the absence of inflammatory cells in cases he studied of infants who died in northern Ireland. He concluded that lethal arrhythmias or conduction disturbances could be due to developmental histologic changes in these critical regions of the heart. Jankus[75] demonstrated lymphocytic infiltrates in the region of the His bundle and left fascicle in a 3-month-old child who died suddenly. However, no degenerative changes were seen and thus the significance of these findings remains speculative.

Giant cell myocarditis is diagnosed when giant cells are found with or without granulomas. Patients with tuberculosis, syphilis, rheumatoid arthritis, rheumatic heart disease, sarcoidosis, and certain fungal or parasitic infections may have granulomas within the myocardium. Giant cells were also described in so-called idiopathic or Fiedler's myocarditis. In a significant number of cases, however, giant cells are found but no specific cause is discovered. There appear to be two types of giant cells, one of which is myogenic in origin and thought to represent a transitional form of myocardial cells. Granulomas are usually not found with these types of cells. The more characteristic type of giant cell is probably derived from interstitial histiocytes and is usually found in patients with myocarditis not due to viral agents. Similar cells were noted in an adult who had received neomercazole therapy,[56] and there has been a report of granulomatous myocarditis associated with phenylbutazone ingestion.[76]

PATHOPHYSIOLOGY

Myocardial function is usually reduced in the presence of extensive interstitial inflammation or injury, resulting in cardiac enlargement and an increase in the end diastolic volume. Normally, this increase in volume results in an increased force of contraction, ejection fraction, and cardiac output, as described by the Starling mechanism. However, in the disease state, a reduced cardiac output results from the inability of the heart muscle to respond to these stimuli. Interactions with the sympathetic nervous system may preserve systemic blood flow secondary to vasoconstriction and increased afterload. Congestive heart failure usually ensues with disease progression or with intercurrent infections that cause fever or anemia, which further stress the myocardial reserve. The progressive increase in end diastolic volume and pressure results in increasing left atrial pressure, which is transmitted into the pulmonary venous system. The resulting increasing hydrostatic forces overcome the colloid osmotic pressure that normally prevents transudation of fluid across the capillary membranes. The typical picture of congestive heart failure with pulmonary edema and systemic venous engorgement is common in the more acute forms of myocarditis. In some infants and children the initial presentation is that of right heart failure.[77] Echocardiographic examination may demonstrate severe left ventricular dilation during diastole and systole and a decrease in ejection fraction usually can be noted. Evaluation of ventricular function using M-mode echocardiography is useful in the acute setting as well as to assess function during therapeutic intervention. Gutgesell and colleagues have established normal echocardiographic standards for children.[78]

During the healing stages of myocarditis, fibroblasts replace normal myofibers, with resultant scar tissue formation. Reduced elasticity and ventricular performance can result in a picture of continuing congestive heart failure. Attempts to preserve cardiac output may exacerbate ischemia, with sinus tachycardia further worsening the supply/demand ratio for oxygen in the heart muscle.

CLINICAL PRESENTATION

The clinical presentation of myocarditis varies considerably in response to various host factors, including age, gender, and immunocompetence. One end of the spectrum results in a fulminant and rapidly fatal illness; at the other end, the majority of cases probably go unnoticed with no apparent clinical illness. Newborn infants are very susceptible to infection with coxsackievirus B, which could result in the severe form of the disease.[15,16] In addition, infections with rubella,[29] herpes simplex,[32] and toxoplasmosis[56,68] may also result in a severe form of illness in infants.

As previously mentioned, myocarditis may be but one component of a more severe generalized illness with concomitant hepatitis and/or encephalitis.[16,26] The myocarditis may be only a mild clinical disturbance in these cases.[79,80] Brightman et al., during a virologic survey in their institution, found a nursery epidemic of coxsackievirus B5 infection in preterm infants. The disease was clinically unnoticed and discovered only by chance during this survey. No instances of severe myocarditis were seen; all infants recovered fully from their infection. The major symptoms were lethargy, failure to gain weight, and aseptic meningitis. In a review of 25 infants with myocarditis due to coxsackievirus B, other symptoms of lethargy and anorexia heralded the onset of severe disease, highlighting the importance of careful attention to any symptom in the newborn no matter how nonspecific.[16] Fever was recorded in over 50% of the cases in this study, although hypothermia was also noted. Cyanosis; respiratory distress; and/or tachycardia, cardiomegaly, or ECG changes were present in 19 of 23 infants; vomiting was noted in 4.

Clinical manifestations of myocarditis are generally less severe in older infants and children than in newborns.[4,77,81–84] Rapidly fatal illness has been reported in association with myocarditis of unknown etiology,[85] enteroviruses,[86] adenoviruses,[87] mumps,[88] varicella,[66] cytomegalovirus,[89] and diphtheria.[90] The usual clinical picture is either an acute or subacute illness often beginning with a mild respiratory infection and low-grade fever.[91] Initial symptoms in infants include irritability and periodic episodes of pallor, which may precede the sudden onset of cardiorespiratory symptoms. Some children may complain of abdominal pain.[83] The physical examination usually shows the child to be anxious and apprehensive, though some appear apathetic and listless. Pallor and mild

cyanosis may be present; the skin may be cool to touch and mottled appearing. Respirations are usually rapid and sometimes labored; grunting may be prominent. The pulse is thready, although blood pressure may be normal or slightly reduced unless the patient is in shock. Palpation of the chest demonstrates a quiet precordium. Tachycardia is usually present. The heart sounds may be muffled, especially in the presence of pericarditis, and a gallop rhythm is frequently heard. A soft first sound at the apex was found to be the most sensitive clinical sign of myocarditis in one study.[92] It should be noted, however, that a soft first heart sound without evidence of myocarditis may be secondary to a prolonged PR segment seen during many febrile illnesses.[93] With severe ventricular dysfunction, mitral regurgitation may be heard with a pansystolic murmur at the apex. Auscultation of the lungs reveals scattered rhonchi and fine crepitations in the lung bases. Although peripheral edema is rare, hepatomegaly is almost uniformly found. Some infants may have only mild congestive heart failure without evidence of peripheral circulatory compromise, while others have such a mild illness that the only abnormal finding may be a conduction disturbance on the surface electrocardiogram.

DIAGNOSIS

The diagnosis of myocarditis is often difficult to establish but should be suspected in any infant or child who presents with unexplained congestive heart failure. The common occurrence of fever in children clouds the history of a recent viral illness, but if a viral illness is documented in the recent past it should heighten suspicion for the diagnosis.

Electrocardiogram

A sinus tachycardia out of proportion to the level of fever in association with a quiet precordium and a gallop rhythm should strongly suggest the diagnosis. A third heart sound—a common finding in normal healthy children—is usually associated with a relatively hyperdynamic precordium with heart sounds that are increased or crisp. When a prominent third heart sound exists without these findings a significant disturbance in ventricular compliance is usually present and deserves further investigation with a chest film, electrocardiogram, and echocardiogram. Children with myocarditis and congestive heart failure usually have cardiomegaly and pulmonary edema visible on their chest radiograph.

In newborn infants whose first sign of illness may be acute circulatory collapse, the cardiac size may be normal. This may also be true in children who present with an arrhythmia secondary to myocarditis. Stokes-Adams attacks secondary to complete atrioventricular block may also be a presenting sign in myocarditis in children.[94]

When an arrhythmia occurs following a febrile illness, the clinician should be suspicious of the diagnosis and look for other signs of disease.[95,96] One study found significant arrhythmias in five infants with isolated myocarditis.[85] Four of the five infants died, and three of them had paroxysmal atrial tachycardia. Other reports of paroxysmal atrial tachycardia have been reported in patients with viral myocarditis[95,96] as well as in patients with disease due to diphtheria.[90] Atrial ectopic focus tachycardia may mimic sinus tachycardia and should be suspected in a patient with persistent sinus tachycardia and cardiomegaly. Careful inspection of the P wave axis and morphology in a 15-lead electrocardiogram, as well as use of a 24-hour Holter monitor to observe the variance in rate, is essential in helping to establish the diagnosis of myocarditis. Complete atrioventricular block secondary to idiopathic myocarditis,[94,97] rubella.[98,99] coxsackievirus,[100] and respiratory syncytial virus[101,102] has been described. Some of these patients developed permanent atrioventricular block[98,100,101] and required permanent pacing, while in others it was noted to be a transitory finding.[97,102]

The classically described electrocardiographic pattern in myocarditis is that of low-voltage QRS complexes (less than 5 mm total amplitude in all limb leads) with low amplitude or slightly inverted T waves and a small or absent Q wave in leads V_5 and V_6. The low voltage may also be present in the precordial leads.

Karjalainen examined the electrocardiograms of 87 patients, 28 of whom had myocarditis.[103] He found that the most frequent finding was that of T-wave changes consisting of reduced amplitude or inversion in the left chest leads. Sinus tachycardia was the most common arrhythmia, followed by uniform PVCs. Another study[104] described four patterns of ECGs in patients with proven viral myocarditis: 1) normalization even in the presence of severe myocardial damage during the acute stage, 2) ''pseudoinfarction'' patterns with pathologic appearing Q waves and poor R wave progression in the precordial leads, 3) conduction disturbances possibly requiring pacemaker support, and 4) chronic arrhythmias consisting of ventricular tachycardia and supraventricular tachycardia.

The electrophysiologic effects of myocarditis have also been studied in animals. In one study coxsackievirus B3 myocarditis was produced in hamsters.[105] The authors found ST- and/or T-wave changes on the surface ECG in 80% of the animals. The peak changes were seen between days 2 and 4, when mortality was highest. Histologic examination revealed that the inner third of the endocardium was primarily involved, suggesting that subendocardial injury corresponded to the ST- and T-wave changes found on the surface electrocardiogram. In another study, myocarditis was induced in DBA/2 mice with encephalomyocarditis virus.[106] Advanced atrioventricular block, premature atrial contractions, and premature ventricular contractions were all seen acutely. The chronic stage was characterized by sinus tachycardia and low voltage of the QRS complex. In the late chronic stages, QRS voltages returned toward normal, possibly reflecting diminished myocardial edema and/or compensatory ventricular hypertrophy.

ST segment and T-wave changes are sensitive indices of myocardial ischemia; however, they also appear to be nonspecific findings. This is true of the prolongation in the PR segment, as is evidenced by its common occurrence during fever. Scott and colleagues[93] found a 1.49% prevalence of these findings in a group of 737 infants and children with concurrent respiratory tract infections, a finding similar to their control group. Another study demonstrated PR-segment prolongation and T-wave changes in infants and children with pneumonia and no signs of myocarditis.[107] Another nonspecific finding—prolongation of the QT interval—has been noted in acute myocarditis as well as in measles and poliomyelitis[108,109] without myocardial involvement.

Echocardiogram

As mentioned previously, the echocardiogram is essential in helping to establish the diagnosis. Pericardial effusion as a cause

of cardiomegaly can be easily ruled out with either single crystal or 2-D techniques. Depressed ventricular function with dilation of one or more chambers, in the absence of any structural abnormality, helps to establish the diagnosis.

Endomyocardial Biopsy

Magnetic resonance imaging has recently been advocated as a possible screening test to help diagnose myocarditis. Screening of patients with dilated cardiomyopathy using gallium 67 may help to select a subgroup of patients who could benefit from endomyocardial biopsy. The biopsy would then be used to confirm the presence of active inflammation and may aid in tailoring therapy. In one study, 68 patients with a diagnosis of dilated cardiomyopathy underwent 71 parallel studies with gallium 67 scanning and endomyocardial biopsy. A dense gallium uptake was found in 5 of 6 patients whose biopsy samples showed active inflammation. Only 9 of 65 negative biopsies had equivocally positive scans. This translated into a 36% incidence of myocarditis on biopsy with positive scan, versus only a 1.8% incidence of myocarditis on the biopsies with negative scans.[110] This technique has not been used in children yet, but may prove to be a relatively safe and effective method in helping to select children for biopsy.

Cardiac catheterization is probably unnecessary in most cases of myocarditis and potentially dangerous in all patients; if it is performed, acutely ill patients should be stabilized before undergoing the procedure. Infants require study to exclude anomalous origin of the left coronary artery, although recent advances in echocardiography have helped to establish or rule out this diagnosis.

During the past decade endomyocardial biopsy has become a relatively safe and effective means of sampling heart muscle. This technique was introduced in 1962 by Sakakibara and Konno,[111] but did not gain wide acceptance in the United States until 10 years later. The widest application for endomyocardial biopsy is in adult patients as well as pediatric patients who have undergone cardiac transplantation in an attempt to assess the degree of allograft rejection.

The major usefulness of endomyocardial biopsy is to help establish the diagnosis of myocarditis and possibly classify the phase of disease (acute, healed, or chronic). Histologic classification has proved to be difficult and at times controversial. The method of sampling small areas may preclude accurate diagnosis, especially if the disease is focal. In the majority of patients, multiple samples (at least three) are obtained from the right ventricular septum and/or apex. Some authors believe sampling from other areas of the heart, such as the left ventricle, to be more sensitive,[112] but this technique has not been widely applied. A recent study[113] reported the findings of normal myocardium examined with hematoxylin and eosin stain as compared to staining with monoclonal antibodies. These findings supported the data of Edwards et al.[114] who found less than five lymphocytes per high-power field (400×). There was no correlation between the peripheral lymphocyte count and the count of lymphocytes in the myocardium. Specifically, B cells and killer T cells (NK cells) were uncommon, whereas the helper-type T cell (OKT4) predominated over the suppressor/cytotoxic type of T cell (OKT8) in a ratio similar to that found in the peripheral circulation (1:44). Other authors[2,4] have pointed out that endomyocardial biopsy may miss focal inflammation in cases of suspected myocarditis and that a thorough examination of the myocardium (i.e., obtaining as many biopsy specimens as possible) should be performed to get a true estimate of whether a disease process exists.

A major problem with endomyocardial biopsy has been overinterpretation or misinterpretation of the biopsy specimen. Investigators have stressed the importance of complete investigation of biopsy samples because of the confusion between findings in patients with idiopathic dilated cardiomyopathy and those with active myocarditis. In one study, 87% of patients with dilated cardiomyopathy had leukocytic infiltrates.[115] Immunocytochemical techniques using monoclonal antibodies may be a more specific way of investigating biopsy samples.[116] A wide variety of lymphocytes are found within the myocardium. They include the OKT4 (helper/inducer), the OKT8 (suppressor/cytotoxic), the OKT11 (pan T cell), the beta-1 lymphocyte, the natural killer cell, the T200 (panleukocyte), and the macrophage monocyte cells. One study examined endomyocardial biopsies of 80 adult and pediatric patients, 57% of whom had a prebiopsy diagnosis of dilated cardiomyopathy and 29% of whom had a prebiopsy diagnosis of myocarditis.[116] Histologic examination showed that 45% of the patients were normal, 3% had active myocarditis, 4% had borderline myocarditis, 6% had dilated cardiomyopathy, and the remainder had nonspecific or nondiagnostic findings. Immunocytochemical studies were then performed utilizing the panleukocyte marker. These studies correlated with findings from the hematoxylin and eosin stain. They also correlated with the sum of the OKT11, beta-1, NK, and macrocyte monophage cells. In 16 patients thought not to have myocarditis based on findings from examination of tissue stained with hematoxylin and eosin, the immunoperoxidase-positive cells were found to be T lymphocytes of the OKT11 type and monocyte macrophages. However, in the patients with active myocarditis, the largest population of cells was that of the OKT8 type. Those patients also had an abnormal OKT4/OKT8 ratio. These newer techniques will probably be used more frequently in the future and will help to determine specifically the type of lymphocytic infiltrate present in any case.[116]

Recent studies[9,10,117] have employed endomyocardial biopsy to investigate patients who present with occult ventricular arrhythmias and a clinical picture of dilated cardiomyopathy. The establishment of a diagnosis helped tailor therapy with improvement of the arrhythmias in some patients.

Fenoglio and colleagues[118] used endomyocardial biopsy to establish the diagnosis of myocarditis in 34 patients who presented with dilated cardiomyopathy. Classification of these patients on the basis of clinical and histologic findings was performed in an attempt to stratify patients who might benefit from immunosuppressive therapy. Three groups—acute, rapidly progressive, and chronic—were formed and it was found that immunosuppressive therapy was beneficial only in the chronic patients. More recently, Dec et al. studied 27 patients referred for endomyocardial biopsy with the diagnosis of dilated cardiomyopathy.[119] Though two thirds of the patients had a biopsy consistent with myocarditis, there seemed to be no correlation between histologic classification and outcome. More importantly, there was no difference in outcomes between the group receiving immunosuppressive therapy and the group who did not receive these drugs. The biopsy was negative in 30% of the patients in this study who had clinical criteria of myocarditis and was positive in two of five patients without any clinical evidence of myocarditis.[119]

Olsen[120] reviewed 1200 biopsy specimens from patients with a clinical diagnosis of dilated cardiomyopathy and found that approximately 25% had a diagnosis of myocarditis based on critical evaluation of their tissue specimens. Unfortunately, there are no large series of pediatric patients with myocarditis to help clarify this issue.

Most authors agree that in the vast majority of patients with idiopathic dilated cardiomyopathy it is probably the result of previous viral myocarditis. Thus, the present interest in using endomyocardial biopsy technique to help establish a subset of patients with active disease who would benefit from some type of therapy not yet elucidated has some validity.

Laboratory Tests

Though rarely successful, an attempt should be made in each child with the suspected diagnosis of myocarditis to identify the offending organism.[121–125] Early in the course of illness it is possible to isolate the virus from the stool, throat washings, or, rarely, the blood. Active infection is diagnosed when a fourfold increase is found in antibody titer to the virus.

Criteria that would help establish a diagnosis of coxsackievirus myocarditis have been suggested.[36] Two high-order associations were identified: 1) isolation of the virus from the myocardium or pericardial fluid, and 2) localization of type-specific virus in the myocardium, endocardium, or pericardium at sites of pathologic change. Moderate-order associations were present 1) if the virus was isolated from the pharynx or stool and a four-fold increase in type-specific neutralizing, hemagglutination-inhibiting, or complement-fixing antibodies was demonstrated, or 2) if viruses isolated from the pharynx or stool with a concurrent serum titer of 1:32 or greater of type-specific IgM neutralizing or hemagglutination-inhibiting antibodies.

IgM-specific antibody titers to coxsackieviruses B1, 3, 4, 5, and 6 may be identified and are useful in helping to estabish the diagnosis.[124] Antigens in the myocardium may be identified using immunofluorescent techniques.[6] In the chronic state, viral identification is usually unsuccessful.[24]

Though a diagnosis of myocarditis is being entertained, blood cultures should be obtained in any infant with fever and signs of compromised cardiovascular function. A complete blood count should be performed, and a leukemoid reaction may be noted.[126] The erythrocyte sedimentation rate is usually elevated during acute myocarditis, although a normal value does not exclude the diagnosis. Elevated levels of serum glutamic–oxaloacetic and glutamic–pyruvic transaminase can occur and be the result of a generalized viral infection, though they may also be seen during episodes of diphtheritic myocarditis.[127] Creatine phosphokinase and lactate dehydrogenase enzymes should also be measured. One study found that elevations of isozyme 1 of LDH were a specific finding in patients with idiopathic myocarditis.[128]

Differential Diagnosis

Any cause of acute circulatory failure may mimic the presentation of acute myocarditis. Hypoxia, hypoglycemia, and hypocalcemia in newborns may accompany heart failure. Circulatory collapse with shock frequently occurs in cases of overwhelming sepsis in this age group. Serum measurements of glucose and calcium as well as blood cultures if sepsis is suspected should be obtained in infants presenting with heart failure.

Many infants with significant structural defects of the heart (e.g., hypoplastic left heart syndrome, critical aortic valve stenosis) may have no audible murmur when severely ill because of extremely low cardiac output. When cardiac function is improved, however, murmurs as well as a hyperactive precordium and clear, rather than muffled, heart sounds may be apparent. In the evaluation of such patients, echocardiographic diagnosis is essential to rule out structural abnormalities.

Beyond the immediate neonatal period, many other causes of myocarditis are possible. Anomalous left coronary artery arising from the pulmonary artery should be ruled out with echocardiographic or angiographic investigation. Endocardial fibroelastosis, Cori type II glycogen storage disease (Pompe's disease), medial necrosis of the coronary arteries, and left atrial myxoma[129] are among the many diseases that can present with symptoms suggestive of myocarditis. Murmurs may be audible with anomalous left coronary artery or endocardial fibroelastosis. They are usually apical in location, rarely more than grade 3/6, and usually secondary to mitral insufficiency. Endocardial fibroelastosis is impossible to differentiate from myocarditis by clinical presentation alone. Endomyocardial biopsy and angiographic changes of the left ventricle will help to make the diagnosis. The ECG in anomalous left coronary artery may show a pattern of myocardial infarction, with abnormal Q waves in the anterolateral precordial leads. A QR pattern with inverted T waves in limb leads I and aV_L may also be noted.

Pericarditis, which may be secondary to viral illness, occurs in children rather than in infants. The clinical history may be similar to patients with myocarditis. Cardiovascular function, however, is usually less severely compromised for the degree of apparent cardiomegaly owing to the amount of pericardial effusion. Cardiac tamponade may occur in severe cases and may present with circulatory collapse. Pericarditis may coexist with myocarditis—so-called perimyocarditis—and a clinical picture consistent with both diseases may be found. An echocardiogram is essential in establishing whether a pericardial effusion is present as well as to establish left ventricular size and function. Perimyocarditis may be seen with rheumatic fever, collagen vascular, and other autoimmune diseases, as well as with coxsackievirus B disease. Myocarditis has been described with rheumatoid arthritis.[130] systemic lupus erythematosus,[131] and ulcerative colitis.[132]

TREATMENT

Care of a patient presenting with a clinical picture and history strongly suggestive of myocarditis depends on the severity of myocardial involvement. Many patients will present with a relatively mild disease, with minimal or no respiratory compromise and only mild signs of congestive heart failure. These patients require close monitoring to assess whether the disease will progress to worsening heart failure and the need for intensive medical care. Experimental animal studies[21,133] suggest that bed rest may prevent an increase in intramyocardial viral replication in the acute stage; thus, it appears prudent to place patients under this restriction at the time of diagnosis. Normal arterial blood oxygen levels should be maintained for any patient with compromised hemodynamics resulting in hypoxemia.

Although no specific therapy aimed at reversing myocardial injury is currently widely recommended, maintenance of cardiac

output at levels that supply adequate tissue perfusion and prevent metabolic disturbances is essential. In cases of congestive heart failure, digitalis may be used and has effected dramatic improvement in some instances.[72] During periods of acute inflammation, the myocardium may be overly sensitive to digitalis, and thus rapid administraiton to achieve therapeutic levels should be avoided. Generally, the oral route is preferred and a dose of 0.03 mg/kg rather than 0.04 mg/kg should be used as a total "digitalizing dose." Half of this should be given initially and the remaining half given in two divided doses at 8-hour intervals. Maintenance therapy should be tailored at achieving adequate therapeutic serum levels.

Diuretics are frequently administered in conjunction with digitalis to patients in congestive heart failure. Though there is no direct beneficial effect on the myocardium, removal of excess extracellular fluid volume may help to improve cardiac function. Diuretics should be administered cautiously inasmuch as too rapid a removal of extracellular volume may result in shock. In addition, excessive loss of K^+ ion with the diuresis may exacerbate digitalis toxicity. We recommend furosemide in a dosage of 1 mg/kg/dose. Frequency of administration depends on the patient's clinical state; if three times daily dosing is required (total daily dose >2 mg/kg/day), it may be necessary to add a potassium-sparing diuretic such as spironolactone.

Newborns may present in shock. Blood pressure is usually maintained at or near normal levels until late in the course and thus is not a sensitive indicator of the severity of illness. Rather, close attention to the adequacy of peripheral perfusion, heart rate, and urine output will give the clinician a better picture of the hemodynamic status of the infant. Though the hearts of these infants and children generally respond poorly to volume loading, selected patients may temporarily respond to boluses of 5 mL/kg of 5% albumin in Ringer's lactate or a transfusion of packed red blood cells if a concomitant anemia exists. High central venous filling pressures of 12 to 18 mm Hg may be required to sustain adequate cardiac output, in contrast to 5 mm Hg in a child with a normally functioning heart.

When these measures fail to re-establish an adequate cardiac output, a positive inotropic agent is administered. We generally prefer dopamine in a dose of 2 to 10 μg/kg/min to support blood pressure and effect some degree of dilation of the renal vasculature. As the dose increases toward 20 μg/kg/min, dopamine exerts an increasingly dominant alpha-adrenergic effect and may increase systemic peripheral vasculature resistance; therefore, we usually avoid doses above 15 μg/kg/min. Dobutamine, which is a sympathomimetic amine that stimulates $beta_1$, $beta_2$, and alpha-adrenergic receptors, is frequently used in combination with dopamine. Dobutamine exerts significant positive inotropy while reducing left ventricular filling pressure. Its advantage is that it does not effect as positive a chronotropic response as dopamine and seems to cause less ventricular irritability (i.e., less ventricular ectopy) than does dopamine. When used in combination with dopamine at low doses (<10 μg/kg/min), dobutamine, in doses of 10 μg/kg/min or more, may result in a significant increase in ventricular contractility while avoiding a concomitant sinus tachycardia that may compromise cardiac output. For this same reason, isoproterenol is best avoided in these patients, as the resultant sinus tachycardia that in other patients may improve cardiac output may adversely affect it in this circumstance.

Recently, sodium nitroprusside has been used extensively in children, especially in the early postoperative period. Cardiac output is improved by the ability of this agent to reduce systemic arterial resistance and thus ventricular filling pressure. In patients with myocarditis, sodium nitroprusside may be used in conjunction with the above-mentioned positive inotropic agents if hypotension is not present. In addition, bedside assessment of cardiac output using thermodilution techniques after placement of a Swan-Ganz catheter can greatly aid in the pharmacotherapy of the altered hemodynamic profiles in these patients. When chronic oral therapy is possible and hypotension is not present, an afterload reducing drug such as captopril, an angiotensin-converting enzyme inhibitor, may be used with digitalis and diuretics.

Arrhythmias should be treated vigorously. Supraventricular tachyarrhythmias can often be suppressed with digitalis, which has usually been previously administered for the treatment of congestive heart failure. Ventricular arrhythmias are usually responsive to lidocaine, given in a loading dose of 1 mg/kg followed by a continuous infusion adequate to maintain a therapeutic serum concentraiton (1 to 5 mg/mL). If complete atrioventricular block occurs, a temporary transvenous pacemaker should be inserted. Observation over a 10- to 14-day period (in an intensive care unit) for the return of normal atrioventricular conduction is mandatory. A permanent pacing device should be implanted if complete atrioventricular block persists beyond that time; it can be done as an elective procedure when the patient's condition is stable.

Antibiotic agents should not be given unless a bacterial infection is suspected and appropriate cultures obtained prior to initiating therapy.

The use of immunosuppressive agents in suspected or proven viral myocarditis is controversial. No controlled studies have been done in human beings to prove their efficacy. Some animal studies have suggested an exacerbation of virus-induced cytotoxicity in the presence of immunosuppressive drugs, possibly due to interference with interferon production.[134–136]

Using endomyocardial biopsy to diagnose myocarditis, Mason et al. followed the inflammatory response to immunosuppressive therapy with followup biopsies in a series of 10 patients.[137] Eight of the patients received both prednisone and azathioprine; the remaining two received prednisone alone. Clinical and histologic improvement was seen in four patients. Two patients who had their medications discontinued suffered relapses, which were reversed with reinstitution of therapy. One patient worsened while on therapy and died. Although this was an uncontrolled study, the authors noted that the reversal of congestive heart failure in the two patients who restarted therapy was highly suggestive of the beneficial effect of immunosuppressive therapy.[137] Another study found definite hemodynamic and histologic improvement in seven of nine patients treated with a combination of prednisone and azathioprine. However, after discontinuation of therapy for 4 months, only four of seven patients still showed improvement. One patient improved with reinstitution of therapy, while two patients deteriorated.[138] In another study, endomyocardial biopsies were performed in 12 patients with high-grade ventricular arrhythmias and no other known underlying heart disease.[116] Lymphocytic myocarditis was seen in 50% of this group. These six patients were then treated with prednisone and azathioprine. At followup, five of the six patients had been cured of their arrhythmia; this finding correlated with disappearance of their lymphocytic infil-

trates on repeat biopsy.[116] Again, this was an uncontrolled study, but the results implied a causal relationship between therapy and outcome.

One recent study illustrates the confounding nature of this disease.[117] Nine patients were treated with single or combined immunosuppressive therapy. Improvement was seen in four patients; however, six of 18 patients who did not receive therapy also improved, nullifying any statistically significant difference between the two groups.[117]

Kereiakes and Parmley[139] have tabulated the results from most of the studies to date showing the effects of immunosuppressive therapy. Sixty percent of 82 biopsy-proven cases of myocarditis showed improvement with therapy. Patients who had lower grade changes apparently did better than those with greater involvement. Complications associated with immunosuppressive therapy, including opportunistic infections[9,137] and a cushingoid state,[136] should be taken into account before administration of these drugs. Steroids have also been used in diphtheritic myocarditis[140] but have not been shown to be effective in preventing ECG changes or the associated neuritis. Controlled studies are now underway in the adult population to address the usefulness of immunosuppressive therapy; a similar study should be undertaken in children before firm recommendations concerning the use of immunosuppressive therapy in this disease can be given to clinicians.

The prognosis of acute myocarditis in newborns is poor. A 75% mortality was found in 25 infants with suspected coxsackievirus B myocarditis.[16] The highest mortality occurred in the first week of the illness. The six infants who survived had no apparent sequelae, although long term followup was not reported. Older infants and children have a better prognosis, with a mortality rate between 10 and 25% in clinically recognizable cases. Hastreiter and Miller[60] reported complete recovery in 50% of their patients. Twenty-five percent of the patients continued to have an abnormal ECG or chest radiograph even though they were clinically asymptomatic. Abnormalities in the resting ECG may not be seen, but may be brought out with exercise.[141] Adult patients who recover may be asymptomatic at rest or with light exertion but may demonstrate a reduced working capacity with exercise stress testing.[142]

The cause of the disease may affect prognosis. Patients who develop conduction abnormalities or arrhythmias with diphtheritic myocarditis have a poor progrnosis; some investigators report a 100% mortality rate in patients with conduction disturbances[127] or supraventricular tachycardia.[90]

CHAPTER 92

Pericarditis

William W Pinsky
Richard A Friedman

The pericardium is a bag that surrounds the chambers of the heart, the origins of great arteries, and the junction of the heart with the systemic and pulmonary veins. Although many diseases can affect the pericardium, including trauma, neoplastic diseases, drug-induced diseases, connective-tissue disorders, sensitivity states, autoimmune diseases, metabolic problems, and congenital abnormalities, the infectious diseases are most important in the pediatric population. Therefore, this chapter discusses in detail the causes and pathophysiology of infectious pericarditis. Other chapters in this book deal with pericardial tumors and postpericardiotomy syndrome including the anatomy and function of the pericardium as well as the physiology of pericardial effusion and some aspects of constrictive pericarditis.

Inflammation of the pericardium may result from a variety of nonbacterial microorganisms or may even occur with a number of noninfectious illnesses. In any case, the responses of the pericardium are limited to: 1) acute inflammation, 2) effusion with or without tamponade and, 3) fibrosis with or without constriction.[1] Untreated purulent pericarditis is rapidly fatal. Therefore, it is important to suspect the disease early and approach the diagnosis aggressively. This aspect of pericarditis will be stressed in this chapter.

ANATOMY AND FUNCTION

The pericardium is composed of two loosely approximated layers, the visceral and the parietal pericardium. The visceral pericardium is made up of mesothelial tissue that closely follows the contour of the heart and extends for a short distance beyond the atria and ventricles onto the great vessels. The outer parietal pericardium is a more fibrous structure composed of layers of collagen interlaced with elastic fibers. The pericardial sac is attached to the diaphragm below, the sternum in front, and the thoracic vertebrae, esophagus, and aorta posteriorly. It is surrounded by the lungs on either side and is related closely to the main bronchi and the mediastinal lymph nodes. The phrenic and vagus nerves supply a network of pain fibers to the parietal pericardium.

The dynamics of the pericardial fluid are poorly understood. The pericardial membrane is active in the transfer of water, electrolytes, and relatively small molecules. Fluids of large molecular weight, however, are absorbed poorly from the pericardial space since lymphatic channels are sparse and drainage must occur primarily through the epicardial capillaries.[2]

The function of the pericardium has been summarized by Ainger:[3] 1) prevention of overdistension of the heart, 2) protection of the heart from infection and adhesions, 3) maintenance of the heart within a fixed geometric position within the chest, and 4) regulation of the interaction between the stroke volumes of the two ventricles.

POPULATION AND INCIDENCE

In an extensive literature review of purulent pericarditis, Boyle reported that approximately half of 425 cases occurred in children younger than 13 years of age.[4] Nonetheless, acute purulent pericarditis is diagnosed infrequently. Pericardial disease of all etiologies occurs approximately once per 850 hospital admissions.[5] From 1962 to 1974, 67 cases were recognized at St. Louis Children's Hospital.[5] Twelve of these children (18%) had purulent

pericarditis. There appears to be a predominance of cases in children under 2 years of age. Keith observed that 90% of acute pericarditis in these infants is purulent.[6] A marked male predominance (77%) at all ages is reported by Boyle;[4] however, the review by Gersony and McCracken of 50 infants with purulent pericarditis indicates nearly equal sex distribution (56% males).[7] Feldman et al.[8] showed a 57:43 distribution of males:females.

ETIOLOGY

Primary purulent pericarditis is rare and accounted for only 7 of 50 cases reported by Gersony and McCracken.[9] The disease is associated most often with infection from another site with hematogenous or direct spread to the pericardium. Feldman[8] reviewed all cases of bacterial pericarditis reported in the English language literature from 1950 to 1977. Including his 6 cases, 162 reports were cited. Bacteria were isolated in 146 of 162 cases (90%). No other infection was found in 10 patients. The most common concomitant site involved was the lung, especially for Staphylococcus aureus, Hemophilus influenzae, and Streptococcus pneumonae. When septic arthritis, osteomyelitis, or skin infections were found, S. aureus most often was the cause of pericarditis. Neisseria meningitides and H. influenzae most often were responsible for concomitant meningitis and pericarditis.

Prior to the introduction of antibiotics, the pneumococcal and streptococcal organisms were the most frequent causes of purulent pericarditis in children. The majority of cases were associated with pulmonary infections. Nearly half the patients with streptococcal pericarditis were associated with postinfluenza pneumonia. Hemolytic streptoccoci were isolated most often, whereas 10% were nonhemolytic streptococci and 5% were Staphylococcus viridans.[4] Kauffman et al. reviewed 113 cases of pneumococcal pericarditis reported since 1900.[10] Preceding pneumonia was present in 93% and empyema in 66%. Pericarditis was felt to be a late event resulting from delay in appropriate therapy for pneumonia.

S. aureus is the most common organism responsible for purulent pericarditis in children.[4,7,8,11,12] Prior to the use of antibiotics, it was responsible for only 17% of cases.[4] Most cases result from hematogenous seeding of the pericardium from staphylococcal pneumonia with empyema, acute osteomyelitis, or soft-tissue abscesses. Occasionally, the pericardium is infected during the course of staphylococcal endocarditis. S. aureus is the organism recovered most frequently when purulent pericarditis develops within 3 months of open heart surgery. The clinical course of acute staphylococcal pericarditis is dominated by severe toxemia. In addition to the necrotizing infection produced by S. aureus, the organism often releases a potent exotoxin which produces shock and contributes to the high mortality. S. aureus was isolated from 73% of infants who died of purulent pericarditis in the series reported by Gersony and McCracken.[7] It was responsible for 50% of cases in children between 1 and 4 years of age in the review by Feldman.[8] In seven cases in children younger than 1 month of age, S. aureus was isolated in four. This finding is corroborated in more recent literature from other countries. A review of 53 cases in Nigerian children found S. aureus and Mycobacterium tuberculosis to be equally as common.[13] In New Guinea, 100% of patients less than 18 years of age between 1979 and 1982 had S. aureus isolated as the causative agent.[14] In both reviews, coincident lung infection was found most commonly.

The second most frequently encountered organism is H. influenzae, usually type b. It was responsible for 22% (35 of 163) of the cases in Feldman's review.[8] Of the 18 isolates that were typed, all were type b. A single site of coexisting infection, the lung, was seen in 16 of 35 cases. Meningitis, as a single other site, was found in 5 of 35 and multiple involvement was found in 7 of 35 patients.[5] Cheatham et al.[15] reviewed nine cases of pericarditis in children due to H. influenzae between 1975 and 1979. Seven of the nine patients were younger than 1 year of age and 7 of 9 had either an upper respiratory tract infection or pneumonia diagnosed 6 weeks to 2 days prior to the onset of illness. Two patients had coexisting meningitis. Interestingly, in the reviews from New Guinea and Nigeria, H. influenzae was not found as a cause of pericarditis in children.[13,14]

Dajani et al.[16] reported that in 292 cases of H. influenzae disease, no cases of pericarditis were found, and other authors have reported only 3 cases of pericarditis in 83 consecutive cases of H. influenzae disease. Leggiardo et al.[17] recently reported two cases of H. influenzae pericarditis developing in children while they were receiving intravenous ampicillin for suspected sepsis. Thus, it is apparent that H. influenzae is becoming an increasingly more common agent responsible for pericarditis in the 1980s than in previous decades. Echeverria et al. summarized 33 cases from the literature.[9] Pulmonary infiltrates and empyema were seen in 64% of patients. Nearly 85% had symptoms of an upper respiratory infection in the preceding 5 to 12 days.

Pneumococcal, streptococcal, and meningococcal pericarditis have diminished in frequency since the introduction of penicillin.[4] Pericardial involvement occurs in about 5% of young adults with meningococcemia.[18,19] The clinical course generally is milder than that observed with other types of purulent pericarditis. Pericardial involvement rarely is present at the time of hospital admission. Pericarditis became apparent by the third day in 13 of 17 patients reported by Dixon and Sanford. In some, it did not occur until late in the course of therapy. Whether this late-onset pericardial effusion is a part of the meningococcal infection or is related to penicillin hypersensitivity has been debated in the literature.[18,20–22]

Occasionally, other microorganisms may cause acute purulent pericarditis. Feldman[8] reported that 11 of 146 cases (8%) of pericarditis in children were due to Pseudomonas aeruginosa. It can occur with pneumonic tularemia, salmonellosis, sepsis from enteric bacilli, listeriosis, and disseminated gonococcal disease.[4] Anaerobic bacteria also should be suspected when pericarditis develops in association with lung abscess, intra-abdominal infection, or a penetrating wound. Callanan et al.[23] reported the rapid development of constrictive pericarditis after purulent pericarditis due to anaerobic streptococcal infection. The child had a history of blunt trauma to the chest 3 weeks before developing cardiac tamponade with no evidence of a penetrating wound. The incidence of anerobic infection may be underestimated due to improper handling of specimens for culture.[8]

Mycobacterium tuberculosis, once a common cause of acute pericarditis in the United States,[24] now is responsible more often for chronic pericardial disease. It is a complication of miliary tuberculosis and, rarely, a primary infection. In the series of 2500 children with tuberculosis reported by Lincoln,[25] pericarditis was diagnosed in 0.4% and found at necropsy in 5% of patients. A review of 100 cases of tuberculous pericarditis in South African blacks by Desai et al.[16] revealed a marked male predominance

(72%). The duration of symptoms in the vast majority of patients was from 0 to 120 days and consisted of cough and peripheral edema. Most patients were febrile and in congestive heart failure. Generalized lymphadenopathy was seen in nearly 30% of patients, pulses paradoxus in half and a friction rub was audible in 25%. Of the 52 patients who had pericardiocentesis, 40% yielded fluid but none were positive for acid-fast bacilli. Pericardial effusion was demonstrated in 82 patients, 16 of whom died of tamponade and another 16 of whom went on to develop constricting pericarditis.

Orbtals and Auroli[26] describe the four stages of tuberculous pericarditis as follows: 1) dry, 2) effusive, 3) absorbtive, and 4) constrictive. Granulomas usually are found in the dry stage and heal with no sequelae. The effusive stage is common with tuberculous lymphadenitis and usually 15 to 200 ml of fluid accumulates in the pericardial space. The absorptive stage is characterized by thickening of the pericardium with fibrin deposition. Further fibrin deposition plus calcification occurs during the constrictive phase. The disease may progress through all stages or remain in one stage alone.

Latent infection in the mediastinal lymph nodes with spread directly into the pericardium is thought to be the mode of involvement with M. tuberculosis.[26] The lymph nodes at the tracheal bifurcation are often the source.

Histoplasma pericarditis generally occurs with pulmonary rather than disseminated disease.[27] Coccidioidomycosis[28] and, rarely, blastomycosis[29] also may cause pericardial disease. Other pathogenic fungi include Aspergillus and Candida. These are more serious considerations in patients who are immunosuppressed or are on long-term broad-spectrum antibiotics or following cardiac surgery.

PATHOLOGY AND PATHOGENESIS

Pericarditis begins with fine deposits of fibrin adjacent to the great vessels; this causes the pericardial membrane to lose its smoothness and translucency. Numerous granulocytes may extend into the myocardium.[30]

Bacterial pericarditis most commonly results from direct extension of infection from involved lung and pleura. Pulmonary infections may spread to the pericardium through the bronchial circulation.[31] Pericarditis frequently arises, however, from infection elsewhere that is transmitted hematogenously. It also may result from immunologically induced antibody response to a primary infection.

As pericardial fluid accumulates, intrapericardial pressure rises. The rate of rise is a function of both the speed of accumulation and the compliance of the pericardium. With slow accumulation of fluid, large volumes can be accommodated because of the gradual expansion of the parietal pericardium. As the compliance of the pericardium reaches its maximum, however, further accumulation of even small volumes of fluid results in an abrupt increase in intrapericardial pressure. If pericardial fluid accumulates rapidly, marked elevation in intrapericardial pressure may occur with much smaller volumes of fluid. As little as 100 ml can cause severe tamponade in a small child, whereas up to 3 L may accumulate slowly in an older child and not result in tamponade.[3]

The most significant hemodynamic effect of pericardial effusion is restriction of ventricular filling. Ventricular end-diastolic, atrial, and venous pressures rise on the right and left heart equally. When restriction to ventricular filling becomes more pronounced, there is a fall in ventricular stroke volume and cardiac output. In an attempt to maintain cardiac output, tachycardia and peripheral vasoconstriction are seen. In addition, systemic arterial blood pressure and pulse pressure are reduced markedly.

Tamponade occurs when these compensatory mechanisms fail to maintain adequate cardiac output.

CLINICAL MANIFESTATIONS

A diagnosis of purulent pericarditis should be suspected in any patient with septicemia who develops cardiomegaly. The classic signs and symptoms of pericarditis are as follows: 1) precordial pain, 2) pericardial friction rub, 3) evidence of cardiac fluid, and 4) muffled heart sounds.[32] Chest pain is not a frequent symptom, especially in young children; the reported percentages vary from 15 to 80.[2,4,6,7,12,33–35]

The most common symptoms and signs of pericarditis are fever, tachypnea, and tachycardia. These also are presenting features of associated systemic infection. However, if there is enlargement of the cardiac shadow radiographically, with or without a friction rub, and the tachypnea and tachycardia are out of proportion to the fever, either myocardial dysfunction or pericarditis should be suspected. An evanescent or ubiquitous rub may be present. The typical sound of a rub is that of a high-frequency murmur[36] that may be to and fro or triphasic but may not have any correlation with the cardiac cycle.[37] The rub frequently is heard better with the patient leaning forward or kneeling.[37] A rub may be differentiated from a murmur by pressing the diaphragm of the stethoscope firmly against the chest wall; this amplifies the rub, and the typical scratchy quality becomes more apparent as one opposes the visceral and parietal pericardium by compression of the chest. Rubs have been known to increase with inspiration.[38] Although it is generally true that a rub is less likely to be heard when there is a large effusion, it still may be present.[37] The heart sounds usually are muffled, and the palpable ventricular impulse generally is diminished. Both of these findings, however, may be found in congestive heart failure; they may be absent with tamponade.

Signs of cardiac tamponade may be an early complication of pericarditis in association with a systemic infection. Cardiac tamponade means that there is compression of the heart by a tense pericardial sac, usually full of fluid, resulting in a decrease in venous return to the cardiac chambers and a decrease in cardiac output. During inspiration, intrathoracic pressure falls, and there is an increase in venous return to the cavae. The tense pericardial sac limits the amount of blood that can enter the right atrium because of diastolic compression; therefore, there is a paradoxic rise in jugular venous pressure during inspiration (Kussmaul sign)[39] (Fig. 92–1).

During inspiration, there is normally a small drop in systolic blood pressure and cardiac output due to an increase in pulmonary venous capacitance. This is exaggerated with pericardial tamponade (greater than 10 mm Hg drop in blood pressure) because of the restricted inflow into the cardiac chambers. This clinical sign has been called paradoxic pulse, but it is actually an exaggeration of the normal respiratory cycle[40] (Figs. 92–2A and 92–2B).

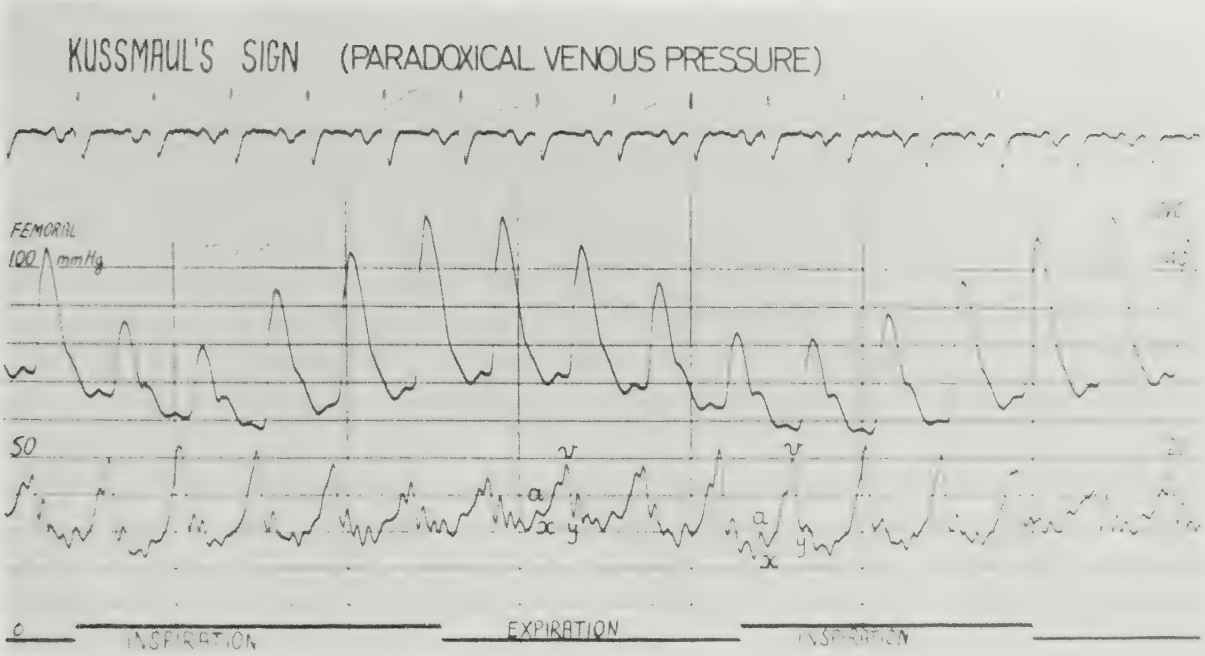

Fig. 92–1. Simultaneous recording of right atrial and femoral artery pressures. Note the increased V wave and exaggerated decrease in femoral artery pulse with inspiration.

DIAGNOSIS

Radiographic appearance of a rapidly increasing cardiothoracic ratio without increasing pulmonary vascular markings is more suggestive of pericardial effusion than congestive heart failure secondary to myocardial dysfunction (Fig. 92–3). Fluoroscopy alone is generally of little value; both myocardial dysfunction and pericarditis can impair cardiac contractility.

The size of the pericardial shadow does not necessarily indicate the severity of hemodynamic effects. This is a function of the rapidity of accumulation and the volume of pericardial fluid. Thus, when acute infection results in sudden cardiac tamponade, heart size may be normal. A large globular heart shadow with no evidence of increased pulmonary vasculature—particularly in a patient who has signs of right heart failure—strongly suggests pericardial disease. The lack of pulmonary overcirculation will help to distinguish this from myocarditis; however, this may be difficult to determine if there also are pulmonic infiltrates.

Lane and Carsky demonstrated the potential of a plain lateral chest film to demonstrate pericardial effusion.[41] The anterior mediastinal and subepicardial "fat stripes" were separated by more than 2 ml in 27 of 42 cases of proven effusion. However, 5 of 15 "negative" films and none of the "positive" films were seen in patients with purulent pericarditis. Obliteration of the retrosternal space without evidence of thymic or right ventricular enlargement also suggests pericarditis.

LABORATORY EVALUATION

Electrocardiogram

The extent of electrocardiographic abnormalities may be explained by the amount of pericardial effusion and the presence of superficial myocardial injury or myocarditis. Pericardial effusion gives rise to low-voltage QRS complexes. This is the result of the damping effect of pericardial fluid between the chest wall and the myocardium. Accumulation of fluid and fibrin under pressure also may produce an injury pattern manifest by ST segment deviation. Over 90% of patients have elevation of the ST segment, which occurs most frequently in leads I, II, V_5, and V_6. Widespread T-wave inversion indicative of epicarditis may be seen in the same leads in which ST segment elevation occurs.

Spodick has described four stages of electrocardiographic changes in acute pericarditis.[42] In stage I, pronounced ST segment elevation is present, and depression of the PR segment may be noted. In stage II, the ST segment begins to return toward the isoelectric line, the amplitude of the T wave diminishes, and the PR segment is depressed. By stage III, the ST segment has returned to the isoelectric line and the T-wave inversion occurs. An incompletely inverted T wave (a diphasic wave or an upright T wave with a notched summit) sometimes is observed. In stage IV, these changes may resolve completely. T-wave abnormalities, however, may persist for life and do not necessarily indicate active disease.

Ginzton and Laks[43] compared the electrocardiograms of 19 patients with acute pericarditis with 20 healthy patients. By forming a ratio of the amplitude of the ST segment and T-wave height in all patients, a value of 0.25 or greater in lead V_6 had a positive and negative predictive value of 1.0 for determining the presence of pericarditis. This also was true in leads I, V_4, and V_5 though the predictive values were not as high as in lead V_6. Using Spodick's criteria in their patients, Ginzton and Laks were unable to distinguish healthy normals from acute pericarditis patients. Their method may therefore prove to be more reliable, though a large study in children has not been performed.

Electrical alternans is seen in the presence of a large pericardial

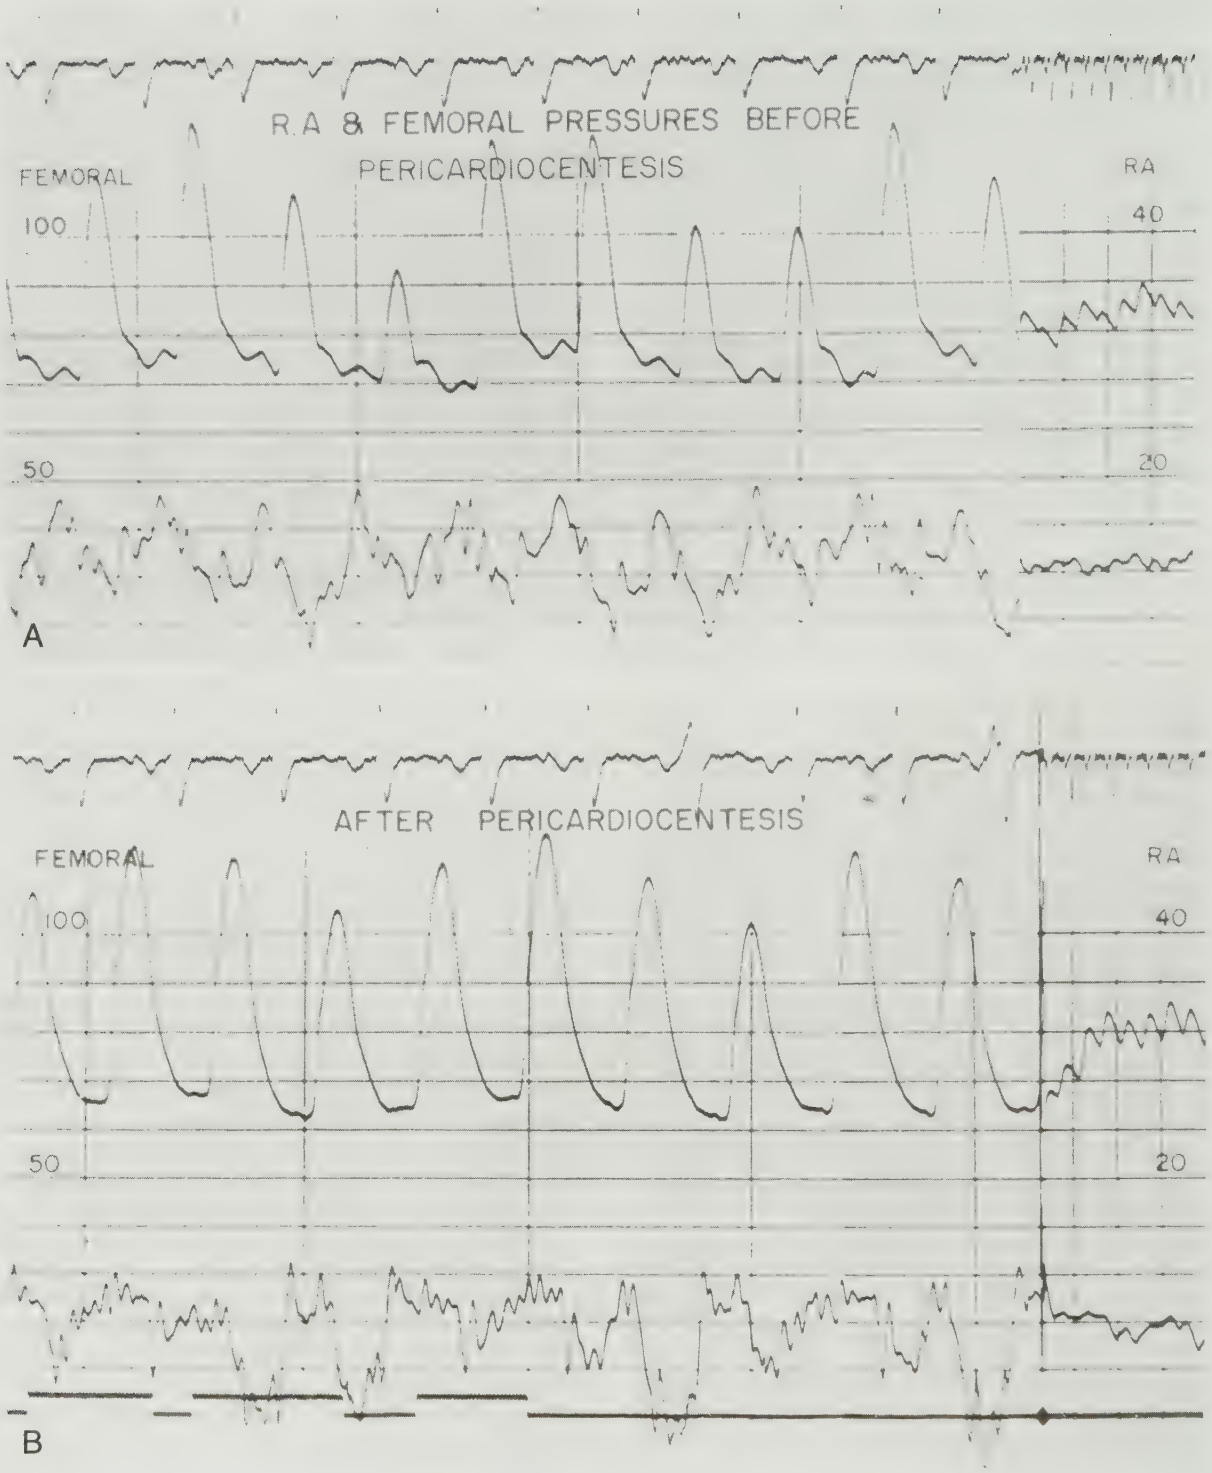

Fig. 92–2. Recordings of femoral artery and right atrial pressures (A) prior to and (B) following pericardiocentesis. In (A), there is an exaggerated decrease in fall of femoral artery pressure with inspiration as well as a sustained increase in right atrial pressure. (B) demonstrates a more normal variation of femoral pressure and a lower right atrial pressure.

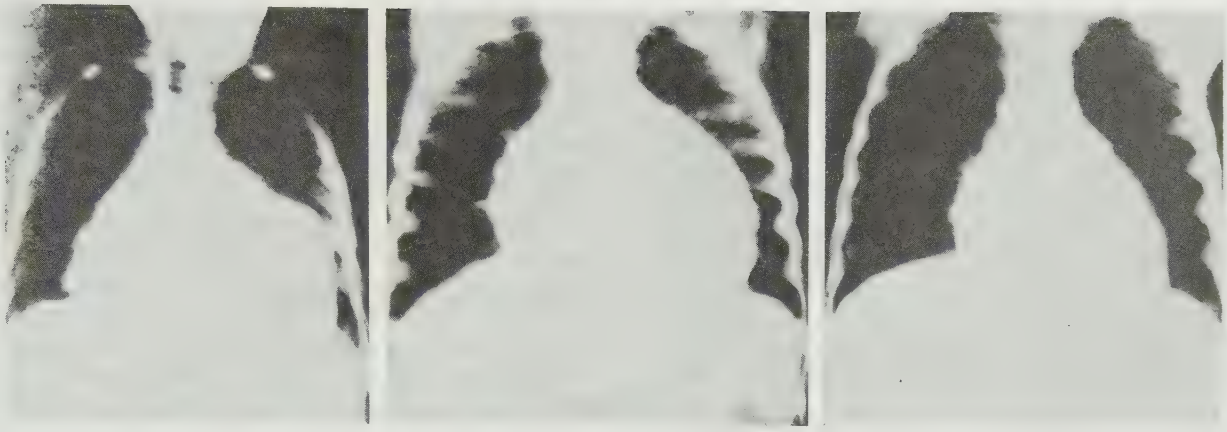

Fig. 92–3. A patient with pericarditis. The first two radiographs demonstrate an enlarged cardiac shadow without an increase in pulmonary vascular markings. The last shows a marked decrease in apparent heart size after pericardiocentesis.

effusion. This refers to the alternation in electric amplitude of the T wave and the QRS complex with each cardiac cycle. Electrical alternans is thought to result from the rotational and pendular motion of the heart suspended in pericardial fluid.

Deviations from classic patterns occasionally occur, but it is not uncommon to have single electrocardiographic changes. For example, all 12 children reported by Okoroma et al. had ST segment elevation, while only 3 had concomitant low voltage.[30]

Spodick[44] has pointed out that although many textbooks cite the frequent occurrence of dysrhythmias with pericarditis, they are an unusual occurrence in the absence of coexisting heart disease. Twenty of 49 patients with acute pericarditis had no underlying heart disease. Seven had no dysrhythmias documented on 24-hour Holter monitoring and 10 of 20 had infrequent single ectopic beats. Only three patients had supraventricular tachycardia.

Echocardiogram

M-mode echocardiography is the most sensitive method for diagnosis of significant pericardial effusion.[45,46] With a small to moderate effusion, only a "fluid space" is noted posteriorly. However, with a greater effusion, fluid is seen anteriorly and posteriorly, and the septal motion becomes grossly abnormal. The heart may give the appearance of freely swinging (Fig. 92–4). Newer echocardiographic techniques, such as two-dimensional sector scanning, are no more useful than the conventional M-mode.

Laird et al.[47] found pericardial effusions on M-mode echocardiograms in 20% of patients with H. influenzae meningitis. The counter immunoelectrophoresis was usually positive for antigen of H. influenzae, and the amount was usually 20 ml or less. However, the majority of cases were asymptomatic and resolved spontaneously with resolution of the meningitis. Thus, the clinical significance of this pericarditis may be minimal. Laird et al. felt that this technique was of limited value in patients without evidence of cardiac involvement.

Radionuclide Imaging

Occult or unsuspected pericarditis also has been discerned with the use of radionuclide techniques. Greenberg et al.,[48] using iridium-111, and Shreiner et al.,[49] using gallium-67, demonstrated the presence of purulent pericarditis in an immunocompromised host and posttraumatic patients, respectively.

Cardiac Catheterization

A pericardial effusion also may be diagnosed by noting a discrepancy between the position of a catheter placed adjacent to the lateral wall of the right atrium and the right cardiac border. An injection of radiopaque contrast material into the right atrium may further delineate these findings. Pressure measurements at the time of cardiac catheterization reveal the elevated right atrial pressure and further emphasize the exaggeration of venous, systemic, and left ventricular pressures imposed by inspiration. Injection of CO_2 or air into the pericardium percutaneously may delineate further the pericardial effusion fluoroscopically and differentiate freely moving fluid from loculated areas (Fig. 92–5). Radionuclide imaging also has been helpful in establishing a diagnosis of pericardial effusion.[50,51]

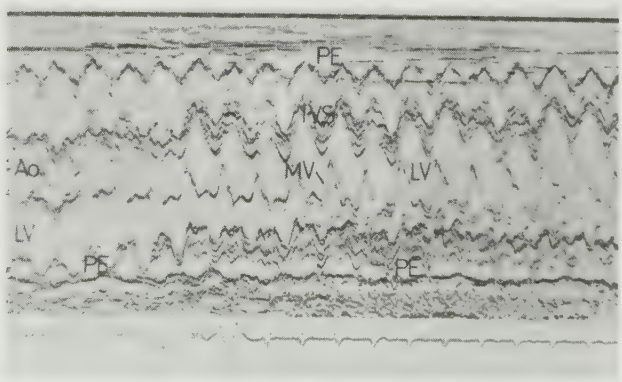

Fig. 92–4. Serial M-mode tracing of a child with pericarditis and pericardial effusion. There is an effusion both anteriorly and posteriorly. Ao—aorta; IVS—Interventricular septum; LV—left ventricle; MV—mitral valve; PE—pericardial effusion.

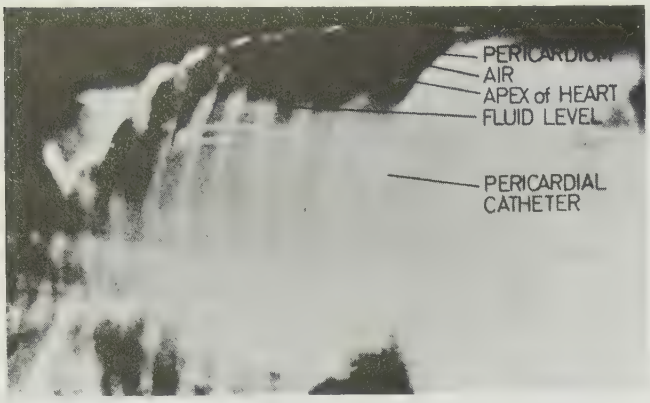

Fig. 92–5. Chest radiograph of a patient lying on right side with a catheter in the pericardium. Air has been injected through the catheter, outlining the pericardium and fluid within the sac.

Pericardiocentesis

The diagnosis of purulent pericarditis is established definitively only by direct examination of pericardial fluid. Purulent fluid is characterized by a predominance of polymorphonuclear leukocytes; however, this also may occur early in the course of viral and tuberculous pericarditis. Proper handling of pericardial fluid is crucial to recovery and identification of the etiologic agent: first, place fluid directly into broth capable of supporting aerobic and anaerobic microorganisms. Fluid also should be plated directly onto agar media such as blood agar, chocolate agar, and MacConkey agar. In addition, cultures should be submitted for M. tuberculosis, fungi, and viruses. Next, several slides should be prepared for immediate examination by Gram stain and stain for acid-fast bacilli. Unstained slides should be stored in case of controversy or the need for special histochemical stains. A sample of pericardial fluid may be submitted for detection of bacterial antigens by latex agglutination or countercurrent immunoelectrophoresis or for detection of staphylococcal techoic acid antibodies. These techniques are useful, particularly if the patient has received prior antimicrobial therapy. The yield from these procedures may be increased by concomitant examination of the serum and urine of the patient.

The causative microorganism is isolated from blood cultures in the majority of patients. When indicated, cerebrospinal fluid also should be cultured. Since purulent pericarditis often follows infections of the lung or pleural space, thoracentesis or direct lung aspirate will reveal the etiologic agent in many cases. Documentation of empyema together with evidence of pericardial disease correlates highly with purulent pericarditis. Van Reken and associates, however, have reported an interesting case of H. influenzae type b pneumonia and empyema in a patient from whom only Coxsackie A-9 virus was isolated from nonpurulent pericardial fluid.[52]

Acid-fast bacilli are present on stained smears of pericardial fluid in 15 to 42% of patients with tuberculous pericarditis.[24] Examination of pericardial biopsy will increase the frequency of identification of M. tuberculosis. Not all patients will react to intermediate-strength PPD (67%) and second-strength skin tests might be necessary. The anergic state seen with miliary disease must be excluded.

Grossly bloody pericardial fluid is noted frequently in patients with Histoplasma pericarditis, and an aspirate of the effusion reveals a predominance of mononuclear leukocytes. Growth of H. capsulatum from pericardial fluid rarely is successful. Elevation of the yeast phase of the complement-fixation titer in pericardial fluid allows a more rapid diagnosis.[27] Serum precipitin antibodies to H. capsulatum also indicate acute histoplasmosis.

DIFFERENTIAL DIAGNOSIS

Any patient with a rapidly increasing heart size in the absence of increasing pulmonary vascular markings should be suspected of having a pericardial effusion. Purulent pericarditis must be differentiated from pericardial effusion due to collagen diseases, other infectious agents (viral, tuberculous, rickettsial, protozoan), neoplastic disorders, metabolic disorders, and congestive heart failure.[8] In addition, glycogen storage disease, congenital heart disease, primary myocardial disease, cardiac tumors, and coronary artery aberrations (anomalous origin from the pulmonary artery, medial wall necrosis, and mucocutaneous lymph node syndrome) may be confused with pericardial effusion.[8] Appropriate analysis of pericardial fluid, as described, generally permits differentiation of purulent pericarditis from pericarditis caused by other disorders.

TREATMENT

Purulent pericarditis is a potentially life-threatening illness that requires the following: 1) pericardial decompression and open drainage, 2) appropriate antimicrobial therapy, and 3) intense supportive therapy.

Ainger has stated that over half the children with purulent pericarditis require early or emergency drainage of the pericardium for relief of critical tamponade.[3] Although bedside needle pericardiocentesis may be life-saving or necessary for rapid diagnosis, Flower and Manitsas have reported three deaths related to pericardiocentesis performed by inexperienced physicians.[37] Complications include arrhythmias resulting from myocardial injury, laceration of the coronary arteries leading to hemopericardium and tamponade, and pneumothorax. Ledbetter[53] has described a 10-year-old girl with staphylococcal pericarditis who developed an aortic aneurysm after multiple pericardiocentesis for recurrent tamponade. The subxiphoid approach is recommended, and Hoffman and Stanger[54] describe the proper technique.

Decompression and drainage of the pericardium is safest in a controlled environment such as in an operating room or under fluoroscopy in the catheterization laboratory. If the patient is awake and agitated, premedication with IV diazepam (1 mg/year of age) or ketamine (0.5 to 1 mg/kg) may be given.

If pericardiocentesis is not successful in relieving symptoms and evidence of tamponade continues, immediate surgical drainage is necessary. Multiple attempts may prove unsuccessful and can lead to serious complications. The pus surrounding the heart may be too thick to be aspirated, as has been seen especially with H. influenzae infection.[55] A surgically created pericardial window with a drain sometimes is necessary to remove completely fluid that accumulates rapidly. While preparing to evacuate the peri-

cardial fluid during tamponade, adequate cardiac output can be maintained by stimulating the heart with pharmacologic agents that cause both a chronotropic and an inotropic effect. Isoproterenol administered intravenously at a rate of 0.05 to 0.10 μg/kg/min is our drug of choice. This does not replace evacuating the fluid but gains time until the aspiration or drainage can be performed. Medications that tend to decrease heart rate and intravascular volume are contraindicated as they further compromise the patient. Wyler[56] warns against the use of halothane anesthesia because of the known depressant effect on myocardial function. He described two patients who had reversible cardiac arrest when this agent was used during surgery to relieve tamponade.

Controversy exists regarding the approach and extent of surgery.[37,57–61] Either a left anterolateral thoracotomy through the fifth intercostal space or a subxiphoid approach with removal of the xiphoid process appears best. Most surgeons favor the creation of a pericardial "window"; however, some favor more extensive removal of pericardial tissue. This decision may be influenced by the severity of pericardial inflammation or the presence of bloody pericardial fluid since these have greater potential for producing acute or chronic constriction. Care must be taken during the procedure not to injure the phrenic nerves. Morgan et al.[55] reviewed 15 children with purulent pericarditis between 1971 and 1981. H. influenzae occurred in 7 of 15 patients. Most patients had pericardiocentesis followed by an anterior interphrenic pericardiectomy and recovered completely. In a series of nine children with H. influenzae pericarditis, all received a limited left thoracotomy with subxiphoid approach for pericardiostomy, and there were no deaths.[15]

It must be emphasized that antimicrobial therapy alone is insufficient for the successful treatment of purulent pericarditis. The survival of patients with purulent pericarditis is improved significantly when early pericardial drainage is performed. In the preantibiotic era, draining the pericardium improved the mortality from nearly 100 to 45%.[4] Occasional patients with meningococcal pericarditis have been managed successfully without pericardial drainage.[20] Fyfe et al.[62] described 73 of 79 patients with H. influenzae pericarditis seen between 1928 and 1984. The mortality before 1960 was 64% (7 of 11 patients), though the majority (5 of 7) were reported prior to the antibiotic era. From 1960 to 1969, the mortality was 36%, and from 1970 to 1979 it droppped to 11.5%. Since 1980, there have been 25 reported cases with 0% mortality. Fyfe et al. note that when surgical drainage techniques were used with antibiotic therapy there was no difference in mortality between patients receiving ampicillin and chloramphenicol versus ampicillin alone. This reflects the absence of ampicillin resistant organisms found in these patients.

When the etiologic agent cannot be detected rapidly, the initial antibiotic regimen should consist of two or more drugs. Since S. aureus is a major pathogen, a penicillinase-resistant penicillin such as methicillin, nafcillin, or oxacillin must be included in a dose of 200 mg/kg/24 hr (maximum, 8 g). For the patient who is allergic to penicillin, vancomycin, clindamycin, or a cephalosporin is substituted; some patients who are allergic to penicillin will be sensitive to cephalosporin. In addition, ampicillin should be administered (300 mg/kg/24 hr) to provide protection against streptococci, pneumococci, meningococci, and H. influenzae. Chloramphenicol should be used when disease due to H. influenzae is suspected, until the sensitivity of this organism to ampicillin can be confirmed. An aminoglycoside antibiotic should be added to this combined drug therapy when purulent pericarditis occurs following cardiac surgery, in association with genitourinary infections or in the immunocompromised host. Duration of therapy is empiric and in part determined by the nature of concomitant infection. Generally, once a pathogenic microorganism has been isolated, the most specific antimicrobial agent is continued intravenously for 3 to 4 weeks.

The chemotherapy of tuberculous pericarditis has had a major impact on mortality. Prior to its use, there was an 80 to 90% mortality in the acute phase and the other 10 to 20% dying from constrictive pericarditis or miliary tuberculosis.[26] Presently, the use of three or four drugs including isoniazid, pyrazinamide, rifampin and possibly streptomycin for a period of 9 to 18 months is recommended. Corticosteroids seem to be helpful in reducing the inflammatory response to infection and enhancing the resorption of pericardial fluid.[26] Prednisone, 80 mg, or equivalent doses of other preparations over 6 to 8 weeks also is recommended. In selected cases, pericardiectomy may be indicated to prevent constrictive pericarditis.

Amphotericin B alone or with other systemic agents is indicated for treatment of fungal pericarditis; however, it rarely is required for successful therapy of Histoplasma pericarditis.

General supportive therapy in the acute stage of infection may include the administration of oxygen, volume expansion to increase ventricular filling pressure, and isoproterenol to facilitate systolic emptying. Digitalis and diuretics should be used cautiously and only when indicated by decreased myocardial function. Serial electrocardiograms may indicate the presence of occult arrhythmias and alert the physician to the degree of myocardial involvement. The patient must be monitored carefully for signs of reaccumulation of pericardial fluid and for the development of acute constrictive pericarditis. Strauss et al. reported this complication in 2 of 12 children with purulent pericarditis.[5] Acute constriction may develop within weeks of the initial pericardial infection[33,63] and has been reported as early as the eighth day.[64] Constrictive pericarditis may be suspected by increasing jugular and central venous pressure, weight gain, enlarging liver, worsening dyspnea, and decreased urinary output. The presence of persistent heart failure when the cardiac silhouette is shrinking also suggests the development of constrictive pericarditis. Complete pericardiectomy should be performed promptly when constriction is suspected.

PROGNOSIS

The current mortality of acute purulent pericarditis ranges from 25 to 75%. Accurate statistics, however, are difficult to compute from the literature since the nature and severity of underlying disease have not been considered. Factors that contribute to mortality are 1) delay in recognition; 2) absence of early surgical drainage; 3) presence of cardiac tamponade; 4) degree of myocardial involvement; 5) the etiologic agent (particularly S. aureus); and 6) age of patient. Long-term followup of children with purulent pericarditis is recommended. They should be followed carefully for the presence of a constrictive component as a sequela to the acute infection. Most children, however, recover fully with a return to normal activity.

VIRAL PERICARDITIS

In 1951, Christian suggested that viral infections were responsible for cases of idiopathic or benign pericarditis.[20] A viral etiology, however, cannot be substantiated in many patients.

Etiology

The principal viruses implicated in pericarditis are the Coxsackie group.[65] Adenoviruses have been recovered less frequently.[66] Previous associations with chickenpox, smallpox vaccinations, influenza,[67] influenza vaccinations,[68] and even infectious mononucleosis[69,70] have been reported.

Clinical Manifestations

Generally, there is a history of upper respiratory infections 10 days to 2 weeks preceding onset of symptoms in about 40 to 75% of cases. Fever and chest and abdominal pain are the most common symptoms.[11,20] A friction rub may be heard in 50 to 80% of cases.[35] Children with viral pericarditis generally are less toxic and experience smaller elevations in body temperature than those with purulent pericarditis. Some, however, appear acutely ill. Large amounts of pericardial fluid accumulation and tamponade are rare.

Investigative Techniques

The electrocardiographic, radiographic, echocardiographic, and nuclear-scanning findings described in patients with purulent pericarditis also are observed in patients with viral pericarditis. The peripheral leukocyte count, however, may reveal fewer polymorphonuclear leukocytes than in patients with bacterial pericarditis. Mononuclear cell infiltrates in the pericardium with extension into the myocardium may be seen.

If obtained, pericardial fluid should be sent for cell count and viral culture. Nasopharyngeal and rectal culture also should be obtained and cultured for viruses. Acute and convalescent serum should be obtained so that appropriate titers can be measured if a virus is isolated.

Course and Prognosis

Viral pericarditis generally resolves spontaneously over a 3- to 4-week period.[65] Large pericardial effusions and tamponade are rare.[32] Generally, bed rest for about 1 week and analgesics for pain are the only required therapy. Corticosteroid therapy rarely is necessary. Constrictive pericarditis is rare. Recurrent pericarditis may develop.[65]

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis involves a thick, frequently fibrotic, and sometimes calcified pericardium.[71,72] This generally leads to restriction in diastolic function of the heart.[71] It is most often a late sequela of purulent pericarditis, and its occurrence in pediatrics is controversial. In a review by Boyle et al.,[4] it was estimated that only 3 to 6% of patients with constrictive pericarditis had a previous documented septic illness in pericarditis. Other investigators have indicated that H. influenzae have led to constrictive pericarditis.[5,63,64] Most likely, the constrictive aspect of pericarditis will occur at least several weeks to months following the acute episode.

Historically, constrictive pericarditis occurs most frequently following tuberculous pericarditis and other forms of purulent pericarditis. It has been documented in from 12 up to 35% of patients with known tuberculous pericarditis.[42] For at least one-half of all patients with constrictive pericarditis, no etiology is found.[42]

The constriction usually is a uniform process and affects all cardiac chambers. It has been reported that there may be localized bands that constrict particular aspects of the heart more completely such as in the atrioventricular groove and aortic and pulmonary valve rings. This may create situations that simulate obstructive valvular disease or obstruction to blood flow returning to the heart such as superior vena cava syndrome or cirrhosis of the liver.[73,74]

The thickening and resulting constricting action of the pericardium lead to decreased diastolic volume and compliance of the ventricles with resulting decreased stroke volume and cardiac output. Intracardiac diastolic pressures will be elevated. Because the pericardium is noncompliant, ventricular filling occurs early but reaches its capacity earlier than normal in the cardiac cycle. Therefore, the diastolic pressure stays the same in mid and late diastole, thus producing the characteristic square root signs in the ventricular pressure curve characteristic of constrictive pericarditis.[71] This constrictive effect to the heart creates equal diastolic pressures in all chambers of the heart as well as the pulmonary circulation. Additionally, the expected fall in systemic venous and right atrial pressures or the increase in venous return to the heart during inspiration does not occur. Although pulsus paradoxus is characteristic of cardiac tamponade, it is not as frequently seen in constrictive disease. The heart tries to compensate for its decrease in stroke volume and potential cardiac output by increasing the rate.[75] However, in severe constriction cardiac output is eventually reduced significantly.[76,77]

Frequently, it is difficult to establish the diagnosis of constrictive pericarditis and differentiate it from restrictive cardiomyopathy. One important differentiating finding in constrictive pericarditis is that the right ventricular and pulmonary artery systolic pressures frequently do not exceed 50 mm Hg.[78] Additionally, in restrictive cardiomyopathy, the left ventricular diastolic pressure generally is at least 5 mm Hg greater than the right ventricular pressure as opposed to constrictive pericarditis, in which the diastolic pressures are similar throughout the heart.[79] Also, the ejection fraction generally is normal in constrictive pericarditis.[80] Sometimes, an endomyocardial biopsy may indicate an infiltrative process, thereby confirming the diagnosis of restrictive cardiomyopathy. However, a normal biopsy cannot necessarily exclude that diagnosis.[79]

Obviously, constrictive pericarditis must be corrected by removal of the pericardium. This should be done prior to the occurrence of long-standing myocardial effects.[81]

CHAPTER 93

Postoperative Inflammatory Syndromes

Sandra K Clapp

There have been great advances in pediatric cardiovascular surgery over the last 30 years. Children with previously fatal cardiac defects can now undergo corrective or palliative operations that enhance both the length and quality of life. With advances in cardiovascular surgery, however, new illnesses have developed that may complicate postoperative recovery. These include postpericardiotomy syndrome and postperfusion syndrome. Common aspects of these illnesses are postoperative fever and malaise, which are generally self-limited. Although rarely fatal, both syndromes prolong postoperative recovery and must be differentiated from other potentially serious operative complications such as endocarditis, wound abscess, pneumonia, atelectasis, and congestive heart failure. The correct diagnosis can be made by recognizing the individual features of each syndrome and by performing appropriate studies to exclude other possible postoperative complications.

POSTPERICARDIOTOMY SYNDROME

Postpericardiotomy syndrome (PPS), the most common of the postoperative inflammatory syndromes, remains a nebulous illness that affects both children and adults in whom the pericardium has been opened. PPS consists of fever beyond the first postoperative week, a variety of symptoms including malaise, pleuropericardial pain, joint pains, decreased appetite, and signs of pleural and/or pericardial inflammation. First observed in the early 1950s in patients operated upon for rheumatic mitral stenosis, PPS was thought to be a reactivation of the rheumatic process.[1,2] Similar findings were described subsequently in nonrheumatic patients undergoing open-heart surgery.[3] Identical illnesses have been reported in patients following myocardial infarction (Dressler's syndrome),[4] and following both penetrating[5,6] and blunt trauma[7] to the pericardium. These illnesses have in common irritation or disruption of the pericardium and underlying myocardium. A common pathogenesis is suspected for Dressler's syndrome, traumatic disruption of the pericardium, and PPS.[5–8]

Incidence

Engle has made major contributions to the understanding of postpericardiotomy syndrome.[3,8–10] A recent report of 400 postoperative children prospectively evaluated for PPS found an overall incidence of 27%.[9] This conclusion agrees with other pediatric and adult series in which the incidence is approximately 30% (range 10 to 60%).[11–17] PPS also has been noted to occur following placement of epicardial leads for pacemaker implantation, although the incidence of this occurence is not known.[18,19] For reasons that are unclear, PPS rarely develops below the age of 2 years, with an incidence in this age group of only 3.5%.[9] Although it may develop following any surgery involving opening of the pericardium, PPS is more common with correction of certain congenital heart defects such as tetralogy of Fallot and ventricular septal defect with pulmonary stenosis.[9] This may be related to the extensive myocardial trauma involved with these operations.[9] Some studies also have noted an increased frequency of PPS in patients who have had prior operations involving the pericardium.[11,16]

Etiology and Pathogenesis

Although there has been much speculation and extensive investigation since the illness was first described, the etiology and

pathogenesis of PPS remain unclear. The original theory that PPS was a reactivation of the rheumatic process[1,2] was disproved when PPS was observed in nonrheumatic patients,[3] and when no supportive evidence of recurrent rheumatic fever could be found.[20–24] Subsequent studies also disproved other secondary infections within or involving the pericardium.[25]

Several authors have noted a seasonal variation in the incidence of PPS and have suggested a new or reactivated viral infection could be involved in its pathogenesis.[8–10,13,15,16] In Engle's group of 400 patients, 70% of those with clinical PPS and antiheart antibodies had a fourfold or greater rise in titer postoperatively to one or more of eight viral agents tested.[9]

Further investigation has suggested that the pathogenesis of PPS might involve an immunologic (autoimmune) component.[8–10,13–15,17,26,27] Many investigators have demonstrated heart-reactive antibodies in the sera of patients who have developed PPS.[8–10,13–15,26,27] The presence of these autoantibodies in high titers correlates well with clinical evidence of PPS.[8–10,13,26,27] Maish, et al.[26] have further investigated the types of autoantibodies and found that 95% of their patients with complete PPS showed antibodies against myocardium and skeletal muscle that included both antisarcolemmal antibodies and antifibrillary antibodies. They noted that antifibrillary antibodies reached a peak 2 weeks after surgery and were primarily IgM, in contrast to antisarcolemmal antibodies, which were predominantly IgG and were seen during the third postoperative week. From the type and timing of appearance of these antibodies in the sera, they suggested that the antifibrillary antibodies are related to a primary immune response after operation whereas the antisarcolemmal antibodies are related to a secondary response.[26]

Opinions differ as to whether the triggering mechanism or "foreign protein" is the surgically damaged myocardium, pericardium, or blood in the pericardial space or a new or reactivated viral inflammation of that same tissue. The end result is proposed to be a delayed hypersensitivity reaction to the foreign stimulating autoantibody production with subsequent development of symptoms.[8–10,13–15,26–29] Other researchers question whether antiheart antibodies cause the syndrome or occur as a consequence of a more diffuse inflammatory process involving circulating immune complexes.[17,27,29–30] It can be summarized from this discussion that further investigation is necessary to determine the exact pathogenesis of this complicated illness.

Diagnosis

Postpericardiotomy syndrome is a febrile illness that occurs 1 to several weeks following an operation in which the pericardium is opened. Although it is usually a single illness, recurrences may occur months or years later.[11,31,32] The fever may be a continuation of early postoperative fever that persists beyond the first postoperative week. Less commonly, there may be a period during which the patient becomes afebrile followed by new fever 2 to 3 weeks postoperatively.[31] The fever is usually between 38 to 39°C orally but may spike as high as 40°C, particularly in children. Lack of agreement regarding other symptoms may explain the variability in incidence between centers.[1–3,8–17] Young children frequently display vague symptoms of malaise, decreased appetite, irritability, and nonspecific chest pain.[11,31,32] In older children and adults, chest pain is a more frequent complaint and includes a tightness in the chest intensified by activity or deep breathing.[11,14,31,32] The pain also may be a more typical pericardial sharp pain radiating to the neck, shoulder, or back, intensified by lying down or swallowing.[14,33] Symptoms of pleuritic pain and arthralgias also may accompany this syndrome.[14,33]

Many patients do not appear particularly ill, but a few can look extremely compromised due to high fever or pericardial tamponade. Other common physical findings include a relative tachycardia, pericardial and/or pleural friction rubs, and evidence of fluid retention such as nonspecific weight gain or hepatic congestion.[11,14,31–33] A pericardial friction rub typical of pericarditis can be heard in most patients at some time during the course of their PPS (see Chapter 92 on pericardial disease). However, the absence or disappearance of the pericardial rub must be taken in the context of clinical progress. It may reflect either healing or an enlarging effusion that separates the epicardium and pericardium throughout the cardiac cycle. Although relatively rare, a few patients progress to pericardial tamponade due to significant pericardial effusions compromising cardiac filling and output. They demonstrate tachycardia, weak thready pulses, shortness of breath, jugular venous distension, hepatomegaly, and other evidence of tamponade as previously described (see pericardial diseases). Pleural friction rubs may be accompanied by dullness to percussion and decreased breath sounds in the area if the effusion is large. The pleural effusion associated with PPS is more frequently noted on the left side.[31]

Findings in the blood may include nonspecific inflammation with a neutrophilic leukocytosis (10,000 to 30,000 WBC per cubic mm) and an elevated sedimentation rate and C-reactive protein.[17] The electrocardiogram may or may not be helpful in children with PPS. Digitalis effect and surgical right bundle branch block frequently mask the subtle electrocardiographic changes related to pericardial irritation. Potential electrocardiographic changes include ST-segment elevation and T-wave flattening or inversion in the limb leads and lateral precordial leads beyond the first postoperative week.[8–10,14,15,31]

Radiographic findings typical of pericardial effusion frequently are seen with PPS. Early or mild changes of cardiac enlargement and increased pulmonary vascularity may be difficult to separate from postoperative congestion. A large pericardial effusion is associated with an impressive enlargement of the cardiac silhouette and widening of the upper mediastinum (see Chapter 92 on pericardial disease). Patients with PPS frequently develop associated pleural effusions that can also be identified radiographically.

Echocardiography has become the hallmark of diagnosis of the pericardial effusion that is invariably present with PPS. Typically, the effusion can be demonstrated by both M-mode and two-dimensional echocardiography. Small effusions separate the epicardium and pericardium posteriorly only during systole, whereas larger effusions cause a separation of these membranes throughout the cardiac cycle and may extend anteriorly.[34,35]

In our experience, pericardial effusion is common postoperatively.[11] We studied 40 children following open heart surgery for congenital heart disease and found an effusion by echocardiographic studies in 21 (53%). In 15 of these patients, effusion was present by the second postoperative day. In general, these effusions were not large; the maximum separation of epicardium and pericardium in 17 of the patients was less than 10 mm in systole. In this study, 18 patients were diagnosed clinically to have PPS, and 16 of these had pericardial effusion. Once present, the effusion

persisted throughout the course of the clinical illness and disappeared as symptoms resolved. The 2 patients who clinically had PPS without effusion had operations with a complicated postoperative course and likely had congestive heart failure instead. Five patients had pericardial effusion without other evidence of PPS. We found echocardiography to be a good screening tool for determining those patients most likely to develop PPS.[11]

Others have found also that pericardial effusion is common postoperatively. Stevenson, et al.[36] studied 39 adult patients postoperatively and found moderate to large effusions in 22 (56%) between postoperative day 4 to 10. In another study of 122 adult patients undergoing cardiac surgery, Weitzman, et al.[37] found that 85% developed postoperative effusions; in 73% of those patients, it was present by the second postoperative day. As in our study, virtually all effusions were present by postoperative day 5, and the vast majority had reached their maximum size by postoperative day 10.[11,37] These authors found that the effusions were echo-free early but frequently developed some degree of echo-density as they peaked in size, suggesting the presence of clotted blood or exudative debris in the pericardium.[37–39] No attempt was made in this particular study to correlate pericardial effusion with symptoms of PPS. However, in our study and in Stevenson's there were a number of patients with pericardial effusion who were not symptomatic. This finding, and the higher incidence of pericardial effusion than PPS, suggests that the presence of pericardial effusion alone is not diagnostic for PPS.[11,36,37] While the presence of a pericardial effusion does not confirm PPS, we do perform an echocardiogram on all postoperative patients within 72 hours of discharge as a screening tool for those most likely to develop PPS and as a postoperative discharge baseline of cardiac function and physiologic repair.

Although PPS and postoperative pericardial effusions are common, cardiac tamponade related to late postoperative pericardial effusion is rare. Of our 40 patients, none had late tamponade, nor did Stevenson's 39 adult patients.[11,36] Weitzman reported only 1 patient with tamponade (day 3) in his 103 patients with postoperative effusion.[37] Others have reported an incidence of late tamponade (after day 7) of 0.1 to 6%, usually in patients requiring anticoagulant therapy,[40–42] and possibly unrelated to PPS.

Constrictive pericarditis does occur late postoperatively in 0.2% of patients,[43] but this does not appear to be related to PPS. None of Engle's 400 pediatric patients developed this complication. She noted that the pericardium in patients who had had PPS did not differ from those of non-PPS patients when examined at subsequent surgery.[9] In a report of 12 patients with constrictive pericarditis postoperatively, Ng, et al.[44] suspected that PPS was an etiologic factor in 4 patients who had PPS following their original surgery. However, a direct relationship was not documented. The high incidence of PPS and extremely low incidence of postoperative constrictive pericarditis makes a direct association of these two postoperative complications unlikely.

While evaluating for PPS, the clinician must remember other causes of postoperative fever and malaise. In a study of 159 adult patients febrile after postoperative day 6, Levelli, et al.[12] found that 35 of those patients had an infectious cause, and another 6 had drug-related fever. Evaluation of prolonged postoperative fever should include blood cultures to rule out endocarditis, chest x ray to assess for pneumonia and atelectasis, and careful evaluation of urine, sputum, and all wounds for signs of infection. Complete blood count, sedimentation rate, C-reactive protein, and echocardiography should be performed simultaneously to assess for PPS and other inflammatory processes. In addition, congestive heart failure must be considered because it can mimic PPS in patients with postoperative malaise, tachycardia, fluid retention, and pleural and pericardial effusions. In some patients, it is impossible to separate congestive heart failure from PPS; these patients may, in fact, have both illnesses. Only after more serious problems of infection and congestive heart failure have been ruled out or treated should the diagnosis of PPS be considered.

Treatment

Postpericardiotomy syndrome is usually a relatively benign, self-limited illness. Its very nature and the subjectivity of symptoms make assessment of therapy difficult. Frequently, only supportive therapy is necessary as the healing process continues. Bed rest has been recommended by some until the fever and pericardial effusion have disappeared.[14] Others have found no difference in duration or progression of symptoms with ambulation and recommend bed rest only if the pericardial effusion is large.[9,45] Diuretics (furosemide) are indicated for symptoms of fluid retention and for pleural and pericardial effusions.[45]

Various anti-inflammatory agents have been used for patients with PPS with symptomatic improvement. Salicylates are administered commonly in children and adults in anti-inflammatory doses (30 to 75 mg/kg/day) for 4 to 6 weeks.[14,24,33,45] Indomethacin has been shown to shorten the duration of postoperative fever and associated symptoms in adults;[12] it has not been evaluated thoroughly in children.

Steroids frequently are recommended for patients with more severe cases of PPS and large pericardial effusions.[14,31,33,45–47] In a double blind study, 12 patients who had severe PPS with elevated antiheart antibodies received either salicylates for several weeks or prednisone 2 mg/kg for the first week, 1 mg/kg for the second week, and 0.5 mg/kg for the third week.[46] The 6 patients who received salicylates soon became afebrile and improved gradually. The 6 in the prednisone group had more impressive responses with prompt resolution of clinical symptoms and findings. Antiheart antibodies in the salicylate group were not altered, whereas in the steroid group the antiheart antibodies dropped to intermediate levels and disappeared earlier than expected.[47] However, caution is recommended in the use of steroids due both to the potential for relapse and their immunosuppressive effect with regard to possible intercurrent infection.[14,47]

In a few patients who develop large or rapidly increasing pericardial effusions, supportive therapy and medications alone may not prevent compromise in cardiac output. As with other etiologies of tamponade, pericardiocentesis can be life-saving (see Chapter 92 on pericardial disease). Once stabilized hemodynamically, these patients usually respond to steroids and other supportive measures. A few may require open pericardial drainage in the form of a pericardial window related to continued compromise of cardiac output. At least one patient has been described who had four relapses of PPS with tamponade requiring repeated pericardiocenteses and three courses of steroids. This patient had total resolution of symptoms only after pericardiectomy.[48] However, the majority of patients with PPS—even those with large effusions—will respond to bed rest, diuretics, and anti-inflammatory agents without the need of surgical intervention. Because recur-

rences and late complications are rare, the overall prognosis remains excellent.

POSTPERFUSION SYNDROME

The postperfusion syndrome is a febrile illness with atypical lymphocytosis and splenomegaly. It typically occurs 3 to 6 weeks after cardiovascular surgery requiring extracorporeal circulation. Due to its late appearance, most patients have been discharged at the time the syndrome occurs. Frequently, the patient is not symptomatic and the illness is discovered at the time of routine postoperative evaluation. The fever is usually low grade at 38° to 39°C and may be accompanied by decreased appetite and vague malaise. In most patients, symptoms are mild, of short duration and do not require readmission to the hospital. The splenomegaly may last up to 3 to 4 months.

Battle and Hewlett[48] first noted this illness in 1958 when they observed the presence of atypical lymphocytes in the peripheral blood smears of five asymptomatic patients who had undergone cardiac operation requiring extracorporeal circulation. The atypical lymphocytes were thought to be similar to the Downey type I and II cells of infectious mononucleosis.[46] Others expanded and clarified the findings of postperfusion syndrome over the next several years to include the triad of fever, splenomegaly, and atypical lymphocytosis after operation, with variable additional findings of hepatomegaly, transient abnormalities of liver function, leukocytosis, hematuria, and albuminuria.[49–57] Eosinophilia, transient maculopapular rash, and adenopathy also have been reported.[52,55,57]

The incidence of postperfusion syndrome is 3 to 8% in most series.[50,51,53–55] Atypical lymphocytes usually are present in the peripheral blood smear at the time of onset of fever. The total leukocyte count is usually normal or only mildly elevated, with lymphocytosis being 25 to 85%. The atypical lymphocytes peak in 1 to 3 weeks and disappear over 1 to 3 months with their actual number ranging from 2 to 19%.[50,51,54–56]

Originally, the etiology of postperfusion syndrome was unclear, but seasonal occurence and many features of the illness suggested a viral etiology.[51,54] Subsequent studies confirmed that cytomegalovirus present in fresh blood used for the extracorporeal circulation or subsequent transfusions allowed transfer of viremia from donor to recipient.[58] This illness has now virtually disappeared with newer techniques for obtaining blood from one to several days before operation.

The diagnosis of postperfusion syndrome can be confirmed by demonstration of cytomegalovirus in the urine and by a changing titer (over several weeks) for the virus in serum. The importance of this benign syndrome is in its differentiation from more serious forms of infection such as endocarditis, wound infection, and pneumonia. An awareness of its typical features in the setting of those rare patients who receive fresh blood during or following operation should make the diagnosis clear. Treatment is symptomatic.

CHAPTER 94

Pediatric Acquired Immune Deficiency Syndrome

I Celine Guerra Hanson
William T Shearer

The acquired immune deficiency syndrome (AIDS), first reported in the literature in a small number of homosexual adults in 1981,[1] has now expanded to affect over 30,000 individuals including children, heterosexuals and intravenous drug abusers. Over 400 children have been afflicted with AIDS and reported to the Centers for Disease Control (CDC), which estimates that these numbers will continue to increase.[2] Children with congenital heart disease may be at risk for pediatric AIDS if they received contaminated blood products prior to the currently implemented blood screening tests that became available nationwide in June 1985. Evidence for cardiac involvement in pediatric AIDS recently has been described. The pediatric cardiologist may be asked to define this involvement in affected children. This chapter gives pertinent information about AIDS in children—that is, etiologic agent, definition and diagnosis, and the implications of this infection in the care of children.

DIAGNOSIS OF AIDS

The CDC has proposed guidelines for the diagnosis of AIDS in children. Pediatric AIDS is defined as a reliably diagnosed disease at least moderately indicative of underlying cellular immunodeficiency, with no known cause of underlying cellular immunodeficiency or any other reduced resistance reported associated with that disease.[3] Those diseases accepted as indicative of underlying cellular immunodeficiency are similar to those listed for adults with AIDS: *Pneumocystis carinii* pneumonia, protracted cryptosporidiosis, atypical mycobacterial infection, and cryptococcal infection. Excluded from this list are congenital infections—specifically, toxoplasmosis or herpes simplex virus infection in the first month after birth or cytomegalovirus infection in the first 6 months after birth. In addition to congenital infections, other excluded conditions are primary immunodeficiency disorders (severe combined immunodeficiency, DiGeorge syndrome, and so on) and known pre-existing secondary immunodeficiency states (i.e., those associated with immunosuppressive therapy or lymphoreticular malignancy). A third criterion for the definition of pediatric AIDS was appended in 1985: histologic evidence of chronic lymphoid interstitial pneumonitis in a child (under 13 years) even if opportunistic disease is absent (as long as the patient has a positive test for human immunodeficiency virus [HIV]).[4] A more detailed classification of HIV infection and its clinical manifestations can be found in a recent CDC publication.[5]

ETIOLOGY

Through the work of separate investigators, the virus responsible for AIDS has been isolated and its genetic mapping elucidated. Montagnier at the Pasteur Institute and Gallo at the National Cancer Institute described LAV (lymphadenopathy-associated virus) and HTLV-III (human T cell lymphotropic virus type-III), respectively.[6,7] Subsequently, these have been identified as the same virus and are now referred to as human immunodeficiency virus (HIV)[8] (Fig. 94–1).

HIV belongs to the family of retroviruses that were first described about 50 years ago. HIV is an RNA virus that acts as an infectious agent in humans by penetrating cell membranes and utilizing the enzyme reverse transcriptase, which is carried in its core to become integrated into the cell's DNA. Genetic mapping of HIV has identified gag, pol, and env genes that are common

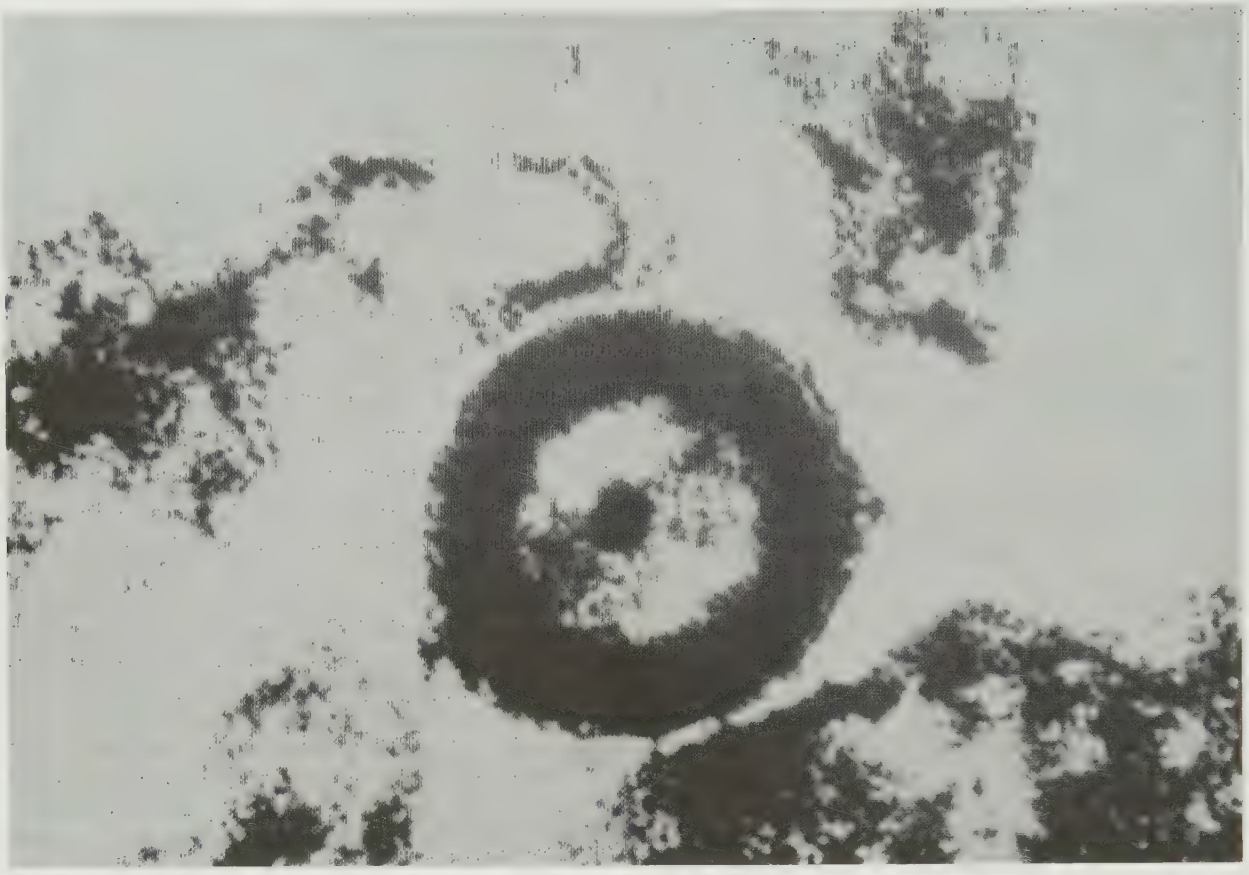

Fig. 94–1. Electron microscopic composite of HIV. (From Gallo, R.C., and Wong-Staal, R., A human T-lymphocytic retrovirus (HTLV-III) as the cause of the acquired immunodeficiency syndrome. Ann. Intern. Med., *103*:679, 1985)

to the human retroviruses and necessary for their replication[9] (Fig. 94–2). Considerable heterogeneity of the env gene and polymorphism have been noted in various HIV isolates, making preparation of an effective vaccine difficult.[10]

Continued research has led investigators to liken the HIV genome to that of Visna, a Lentivirus that infects sheep and, like HIV, has tropism for lymphocytes and central nervous tissue.[11] Although HIV has been isolated repeatedly from affected AIDS patients and those with AIDS-related complex (ARC), to date infection with the virus has not induced clinical AIDS in any animal model. Commercially available serologic tests measure human antibody response to the antigens of HIV.[9] The envelope proteins are those with the greatest immunogenicity and, as would be expected, antibodies to these antigens are most commonly encountered in patients with AIDS.[12]

EPIDEMIOLOGY

Epidemiologists have successfully assigned risk factors to greater than 95% of all reported AIDS cases (Table 94–1). Risk groups have included homosexual and/or bisexual men, intravenous drug abusers, Haitians, recipients of contaminated blood products (including hemophiliacs), heterosexuals (sexual partners of infected individuals), and children via perinatal transmission. Those children at risk for pediatric AIDS comprise three groups: Group I, children born to mothers infected with HIV (prostitutes, IV drug abusers, women with infected sexual partners, and so on); Group II, children who received HIV-contaminated blood products; and Group III, children who have been sexually abused by infected individuals (Table 94–2). Thus, researchers have concluded that HIV is transmitted by blood and intimate sexual contact.

Over 70% of all reported pediatric AIDS cases are acquired by perinatal transmission (i.e., in utero, during labor, or possibly shortly after birth).[13] In a study of more than 200 children, the age of onset of symptoms and diagnosis ranged from 1 month to 7 years (mean 17 months).[14] Evidence for prenatal transmission has been established with documentation of fetal and placental tissue infection with HIV being made as early as the middle of the first trimester.[15] The precise incidence of perinatal transmission of HIV is not yet defined although it has been estimated as high as 60 to 75%. An HIV-associated embryopathy considered to be

Table 94–1. Risk Factors in Reported AIDS Cases

Sexually active homosexual or bisexual men	65%
IV drug abusers	17%
Homosexual and bisexual IV drug abusers	8%
Transfusions of contaminated blood	2%
Hemophiliacs receiving contaminated blood factors	1%
Heterosexual activity	4%
Perinatal transmission	1%
Total	98%

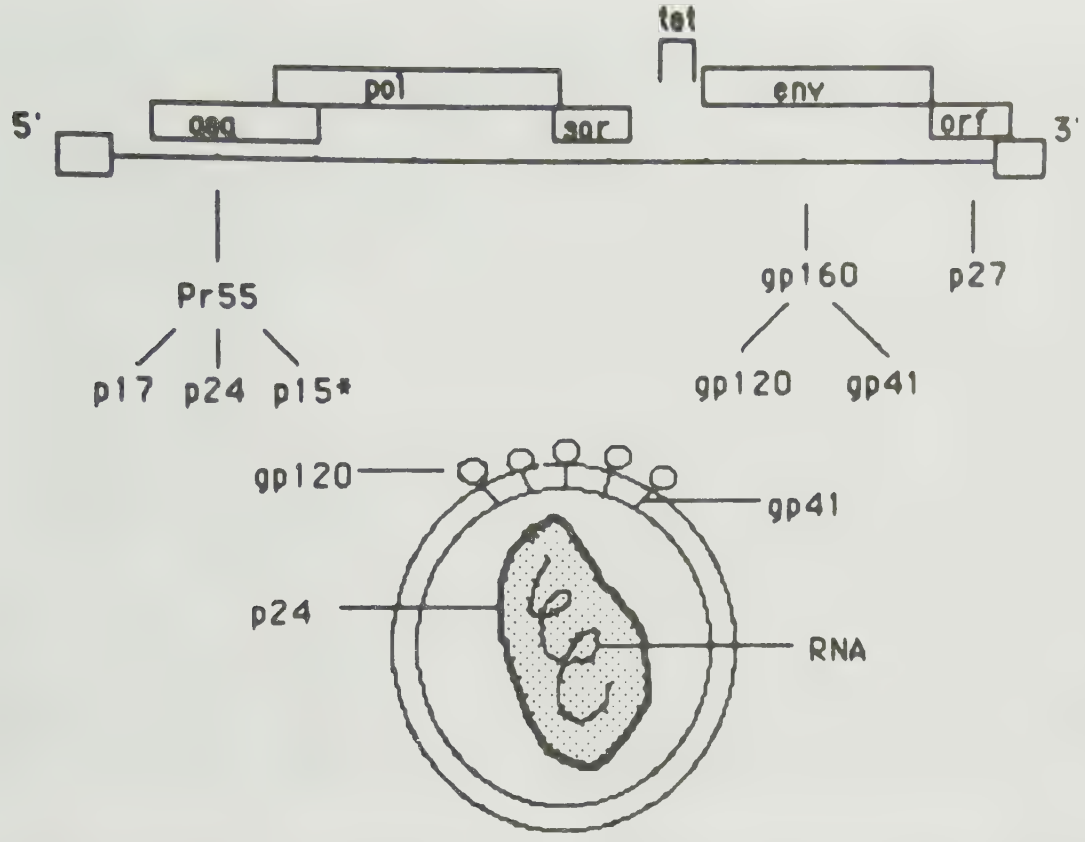

Fig. 94–2. HIV genome and translational products. The proviral genome is depicted with boxes representing known and deduced viral genes. The asterisk marks putative gene products. (From Essex, M., et al., Antigens of human T-lymphotropic virus type III/lymphadenopathy-associated virus. Ann. Intern. Med., *103*:700, 1985.)

distinct from fetal alcohol syndrome has been reported in the literature in a small number of these children.[16] Associated physical findings in HIV-associated embryopathy include growth failure, hypertelorism, boxlike forehead, flat nasal bridge, patulous lips, and microcephaly. These children are at risk for development of AIDS cardiac involvement. Additionally, fetal and postnatal morbidity appers to be increased for infants of mothers with evidence of infection (i.e., seropositive mothers),[17] compared to the general population.

The incubation period for HIV infection appears to be long. Adults with transfusion-associated AIDS have reported onset of symptoms following transfusion to range from 1 month to 5 years, with a mean of 28 months. In contrast, the range for children in a small study (12 children) was shorter, 1 month to 2½ years, with a mean of 8 months.[18] The onset of nationwide screening of blood products for HIV should significantly reduce and almost abolish this route of infection. Although Group III defines a small number of children who have been sexually abused, this possibility cannot be ignored.

Table 94–2. Children at Risk for AIDS

Infants of mothers infected with HIV through bisexual partners, prostitution, IV drug abuse
Children receiving contaminated blood or blood products
Children sexually abused by individuals with behavior at risk for HIV infection

PATHOPHYSIOLOGY

The immunopathogenesis of AIDS is not completely defined but major advances occurred following the discovery of HIV, the etiologic agent. The majority of individuals infected with HIV do not develop AIDS[5] and the incubation period for those who do develop the syndrome can be quite prolonged. Host factors appear to play an important role in determining who develops AIDS. Implicated host factors include pre-existing immune dysfunction and exposure to many antigenic stimuli either by repeated infections or foreign products (i.e., homosexuals, IV drug abusers, neonates, and hemophiliacs).

In adults with AIDS, lymphotropism has been suggested by the associated lymphopenia and decrease in the CD4 helper/inducer subset[19,20] (Fig. 94–3). Children with AIDS are less frequently noted to have absolute lymphopenia but do have selective helper/inducer depression.[21] With this prominent cytopathic effect on CD4+ (previously known as T4+) cells, presumed tropism can be at least partially explained by binding of the viral envelope protein of HIV to the CD4 molecule itself. In fact, experiments using monoclonal antibody to CD4 following incubation with HIV show effective reduction in infectivity, suggesting that the CD4 surface antigen may be a component of the viral receptor.[22] Selective depletion of this helper cell effectively modulates the immune response by decreasing production of the lymphokine, interleukin-2, by decreasing the immune response to soluble antigens, by suppressing mixed lymphocyte reactivity, and by depressing

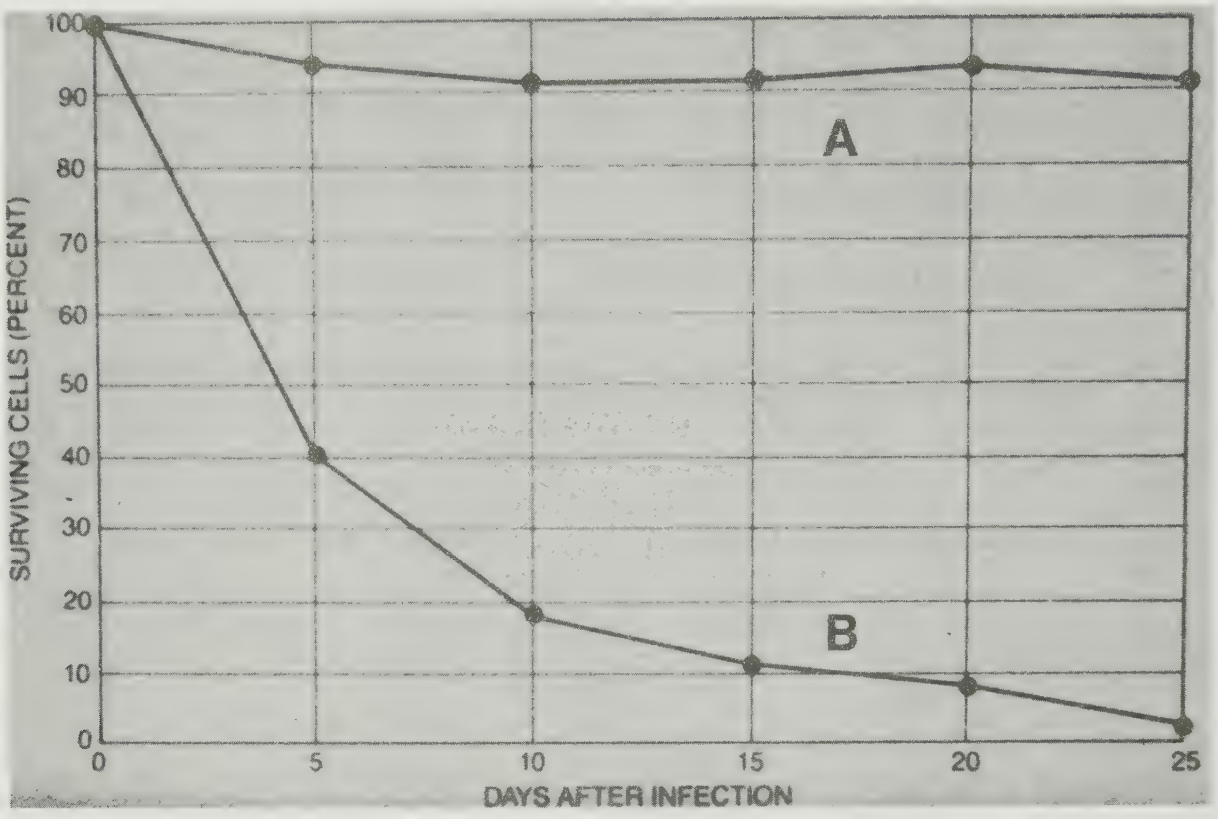

Fig. 94–3. Cell survival in culture after exposure to the AIDS virus differs by cell type. Little effect is noted on the number of CD8+ cells (A) but the number of CD4+ cells declines dramatically (B). (From Laurence, J., The immune system in AIDS. Sci. Am., *253*:84, October 1985.)

the clonal expansion of lymphocytes. In contrast to other viral infections such as Epstein-Barr virus (EBV) and cytomegalovirus (CMV), clonal expansion of CD8+ (previously known as T8+) suppressor/cytotoxic cells is infrequently noted in HIV infection. Thus, an inverted CD4/CD8 ratio characteristic for AIDS is produced by selective depletion of the number of CD4+ helper cells, rather than by an elevation of the number of CD8+ suppressor cells. In addition, suppressor cell function is known to be defective in AIDS patients.

Other cells are affected by HIV in AIDS. For example, in children it appears that the earliest immunologic manifestation of infection involves B lymphocytes with polyclonal stimulation and increased serum immunoglobulins.[23] IgG and IgD are consistently elevated (these elevations are often 4 to 5 times normal for age). IgA and IgM also are elevated frequently. Despite hypergammaglobulinemia, functional B cell defects are noted in some patients, with absence of response to de novo challenge (i.e., absent response to protein and polysaccharide challenge). Clinically, this B lymphocyte defect is manifested by recurrent pyogenic infections, particularly bacteremia. Natural killer cell defects and functional abnormalities of monocytes also have been described in AIDS.

HIV has been isolated in the cerebrospinal fluid, brain, spinal cord, and peripheral nerve of infected patients, suggesting neurotropism[24] in addition to lymphotropism. Several distinct neurologic syndromes have been described in adults with AIDS including chronic meningitis, dementia, and AIDS encephalopathy. In children, progressive encephalopathy with loss of motor milestones and evidence of cortical atrophy on computed tomographic scanning has been described. The pathogenesis of this encephalopathy is purported to include persistent viral infection of the brain, specifically HIV infection.[25] More recent investigations have described HIV isolation from monocytoid cells in the brain tissue of AIDS patients with encephalopathy, lending further credence to neurotropism and the important role of infection of monocyte/macrophages in this syndrome.[26,27]

CLINICAL MANIFESTATIONS

Pediatric AIDS differs clinically from the syndrome described in adults. The most distinct differences are the infrequent finding of lymphopenia or Kaposi's sarcoma in affected children. To date, only two children have been described in the literature with Kaposi's sarcoma.[28] This differs distinctly from adults who present with Kaposi's sarcoma alone or in conjunction with opportunistic infection in greater than 33% of reported cases.[20]

The typical clinical presentation of pediatric AIDS frequently is not clearly distinguishable from other chronic diseases (i.e., cystic fibrosis, primary immunodeficiencies, malnutrition, Crohn's disease, etc.).[23,29] Salient clinical features include failure to thrive, chronic interstitial pneumonitis, hepatosplenomegaly, diffuse lymphadenopathy, protracted diarrhea, salivary gland enlargement, thrombocytopenia, and recurrent otitis[21,23] (Table 94–3). Chronic interstitial pneumonitis has been described in almost 100% of affected children and histologic evidence of lymphoid interstitial pneumonitis (LIP) is a definitive diagnostic criterion of AIDS in children. Attempts to distinguish LIP clinically

Table 94–3. Clinical Manifestations of Pediatric AIDS*

Chronic interstitial pneumonitis	100%
Hepatosplenomegaly	97%
Failure to thrive	94%
Diffuse adenopathy	56%
Protracted diarrhea	39%
Thrombocytopenia	31%
Eczemoid rash	19%
Recurrent otitis media	19%

*Modified from Shannon, K.M. and Ammann, A.J., Acquired immune deficiency syndrome in children. J. Ped., *106*(2):332, 1985.

from *Pneumocystis carinii* pneumonia have included noting a more severe hypoxemia and a higher serum lactate dehydrogenase level in children with *Pneumocystis* pneumonia.[30] In LIP, serologic assays of lung tissue and blood suggest persistent EBV infection. At present, distinction of these two pulmonary diseases in AIDS children is only possible histologically. Chronic interstitial pneumonitis in pediatric AIDS may be confused with interstitial pulmonary edema. Neurologic manifestations have been described in children including progressive encephalopathy, ataxia, and isolated seizures.[25]

The opportunistic infections of pediatric AIDS are not dissimilar from those described in adults, with the exception of exclusion of congenital viral infections (i.e., congenital Herpes simplex, toxoplasmosis or CMV in the first 6 months of life). Associated infections in children have included those due to *Candida* species, *Pneumocystis carinii*, EBV, CMV, gram negative bacteria, *Staph aureus* and *Strep pneumoniae*[21] (Table 94–4). *Pneumocystis carinii* pneumonia along with LIP are the two most common pulmonary diseases in pediatric AIDS. *Pneumocystis* pneumonia is, in fact, the most common infection in pediatric AIDS and is described in 70% of children reported to the CDC.[19] Atypical mycobacterial infections (particularly those due to *M. avium-intracellulare*) were noted in one center's study to affect 8% of children with AIDS under 3 years of age. The incidence increased in older children and in those with progressive decline in immunologic function.[23] Oral thrush is a common finding in infants with AIDS; more severe candidal infections have included sepsis, central nervous system involvement, and esophagitis. Other fungal infections described in pediatric AIDS patients include *Cryptococcus neoformans* (meningitis and disseminated disease) and disseminated Histoplasmosis.[23] CMV infections are considered opportunistic infections in pediatric AIDS when infection is documented outside of lymph node or liver tissue. Clinically, CMV infections have been described in pediatric AIDS in the form of pneumonia and meningitis. Bacterial infections are common and the incidence of sepsis high in children with AIDS. In one study, over 50% of evaluated children with AIDS were reported to be septic; the most common bacterial pathogen was identified as *Streptococcus pneumoniae*.[23]

Laboratory findings in pediatric AIDS include a selective CD4 helper/inducer lymphopenia (absolute lymphocyte count may remain normal), an inversion of CD4/CD8 ratio, and an abnormal lymphocyte function with depressed in vitro responses to mitogens (phytohemagglutinin, concanavalin A) and anergy to delayed hypersensitivity skin test[31] (Table 94–5). Hypergammaglobulinemia is a frequent finding and has been associated in a small number of AIDS patients with IgG subclass deficiencies. The response of B cells to de novo antigen challenge has been abnormal in some AIDS patients, with no rise in serologic titers following immunization with diphtheria, tetanus, and so on. Anemia (frequently Coombs positive) and thrombocytopenia have been described. Serologic testing for HIV is almost always positive both by the screening test (ELISA) and the more specific confirmatory test (Western Blot). The chest radiography typically defines evidence of chronic pulmonary disease with hilar prominence and, often, diffuse interstitial or nodular infiltrates (Fig. 94–4).

Table 94–4. Opportunistic Infections in Pediatric AIDS*

Pneumocystis carinii pneumonia
Candidiasis—esophagitis, meningitis, sepsis
Mycobacterium avium—pneumonia, hepatitis, disseminated
Cytomegalovirus—pneumonia, central nervous system, gastroenteritis
Herpes Simplex (disseminated) ulcerating lesions
Cryptosporidium—enteritis
Toxoplasma gondii—central nervous system, pneumonia
Lactobacillus—sepsis
Cryptococcus neoformans—central nervous system, disseminated
Histoplasmosis (disseminated)
Strongyloidosis—pneumonia, central nervous system, disseminated

CARDIAC COMPLICATIONS

In 1984, the first evidence for cardiac abnormalities in adults with AIDS was reported.[32] Seventy-three percent of the patients evaluated in this study were noted to have cardiac abnormalities, including pericardial effusions (some resulting in cardiac tamponade), increased right ventricular size, and mitral regurgitation (Fig. 94–5). Subsequent studies have described nonbacterial thrombotic endocarditis with embolization to major organs and congestive cardiomyopathy in adults with AIDS.[33,34] Other pathologic findings in adults have included metastatic Kaposi's sarcoma, *Cryptococcus neoformans* myocarditis, and cardiac aspergillosis.[35–38]

Evidence for cardiac involvement in pediatric AIDS has been described and was noted in as many as 63% of patients evaluated.[39] Echocardiographic abnormalities included pericardial effusion and left ventricular dilation with decreased contractility. Left ventricular dysfunction was noted to be the most frequent echocardiographic abnormality.[40] Right ventricular dysfunction is described in association with left ventricular abnormalities and is suggested to be the result of repeated or chronic lung disease,[41] with presumed pulmonary hypertension. Electrocardiographic changes also were frequently noted, including ventricular hypertrophy and complete

Table 94–5. Immunologic Abnormalities in Children with AIDS*

Hypergammaglobulinemia	93%
Decreased lymphoproliferative responses	80%
Reversed CD4/CD8 ratio	78%
CD4 lymphopenia	41%
Hypogammaglobulinemia	3%
Absolute lymphopenia	3%

right bundle branch block (Fig. 94–6). There are, as yet, no reported cases of cardiac malignancy or nonbacterial thrombotic endocarditis in pediatric AIDS.

DIFFERENTIAL DIAGNOSIS

The salient clinical features of pediatric AIDS are noted frequently in many other chronic pediatric diseases. Hence, the differential can be lengthy and include other causes of secondary immunodeficiencies including severe malnutrition, immunologic decline following immunosuppressive therapy, and other viral infections (EBV, CMV).

Remarkable hypergammaglobulinemia is a consistent finding in pediatric AIDS and may help to distinguish AIDS from other early viral infections in children. The selective CD4 lymphopenia and resultant inverted CD4/CD8 ratio also may help to distinguish HIV infection from other viral infections.

Since the discovery of HIV as the etiologic agent of AIDS, serologic assays for HIV have been particularly helpful in piecing together what can present a most confusing puzzle to clinicians. The ELISA (enzyme linked immunosorbent assay), first commercially available in 1985, is an effective screening test with excellent sensitivity and modest specificity for antigens of HIV.[42,43] This is the serologic assay used by blood banks nationwide for screening of blood donors. For this purpose, high sensitivity makes it a most useful tool. The reduction in specificity, on the other hand, limits its potential as a diagnostic test for AIDS, and other serologic assays with enhanced specificity to HIV are used to confirm the ELISA results. These tests include the Western Blot, the cytoplasmic immunofluorescence test, the membrane immunofluoresence test (MIF), and the highly sensitive, although not commercially available, radioimmunoprecipitation assay (RIPA).[9] It is imperative to recall that a positive AIDS test infers HIV infection but does not by itself diagnose AIDS. AIDS is diagnosed by the presence of a constellation of clinical findings of which the serologic data is only a part. The diagnosis of AIDS in adults and children is made by documentation of a T-lymphocyte defect characteristic of HIV infection with associated opportunistic infections or in children associated with chronic lymphoid interstitial pneumonitis.

Confusion results when serologic data suggest HIV infection but pertinent immunologic data is normal and there is no evidence of opportunistic infections in the patient. Therefore the CDC has classified and staged HIV infection and included AIDS as an extreme manifestation of the spectrum of this disease. Information regarding progression of quiescent HIV infection to clinical AIDS currently is not available although it is clear that this data will be forthcoming in the near future.

PRECAUTIONS FOR FAMILIES AND HEALTHCARE WORKERS

The prognosis for AIDS is as dismal in children as in adults; death occurs in over half of the children reported to the CDC. For surviving children, there is another problem with social ostracism caused by public fear and misunderstanding. In an effort to assist with these latter issues, the CDC has proposed guidelines for the schooling and foster-care placement of affected children.[44] Current information on the transmissability of HIV infection documents the *lack* of evidence for a casual transmission of HIV.[45–49] These CDC guidelines include placement of school aged children in schools (classroom, after-school daycare, and so on) and foster homes without restrictions. Re-evaluation of each child on the basis of his/her general health and risk of classroom exposure (i.e., influenza, varicella, and so on) is encouraged frequently since these infections are potentally fatal in immunocompromised

children. Informed primary caretakers are encouraged to practice good handwashing when in contact with bodily fluids of infected children. Paramount in these guidelines is the reminder that the child's right to privacy be maintained and medical records be kept confidential.

As the majority of pediatric AIDS cases (70%) are acquired by perinatal transmission, it is prudent to test other family members, especially siblings, for evidence of HIV infection. However, indiscriminate testing is not warranted and only those defined as household members at risk (sexual partners, parents as potential sources of infection, and siblings) should be screened.

Precautions for the healthcare provider dealing with AIDS patients are similar to those recommended to the healthcare provider for patients with hepatitis B infection (i.e., good handwashing with exposure to bodily fluids particularly blood).[50] Healthcare workers are often at an increased risk to bloodborne infections because of accidental percutaneous exposure to blood (i.e., needlestick injuries). Current data suggest that, even with needlestick injuries, HIV infection is difficult to acquire.[51–54] With these data in mind, guidelines for preventing transmission of HIV in the workplace have be published. Emphasis is placed on education and techniques for avoiding percutaneous puncture.[54] Further recommendations for preventing HIV infection during invasive procedures also have been outlined.[55] Eye protection and gloves for those handling a patient's blood during heart catheterization is prudent.

TREATMENT AND THE FUTURE

The current therapeutic approach to AIDS is supportive—that is, antimicrobial therapy for identified infections and nutritional support for inanition associated with infections. Experimental treatments of AIDS have included immunoreconstitution with bone marrow transplantation, immunomodulatory drugs, viral eradication with antiviral agents, and immunoglobulin replacement therapy in children.[56–58] Some of these attempts have met with failure and others with modest success. Immunoglobulin replacement has been suggested for pediatric AIDS patients, despite their elevated serum immunoglobulin levels, because of the high incidence of bacteremia and B lymphocyte functional defects noted in some infected children. Perhaps a more appropriate practice would be the treatment of only those infected children with identified functional B cell defects.

Attempts to provide a vaccine for the prevention of AIDS has been stymied by viral variability and polymorphism.[59] The advent of an effective vaccine against another retrovirus, feline leukemia virus, has been encouraging.[59] Large-scale education programs dealing with sexual education and IV drug abuse have been launched to provide information regarding transmission of HIV infection. Within the past few years, the medical community has gained an enormous amount of information regarding AIDS. It is hoped that in the future a cure will be available for this infection.

ACKNOWLEDGMENTS

We thank Dr. Ralph D. Feigin and Dr. Howard M. Rosenblatt for their critical reviews of the manuscript.

indications for, 1015-1016, 1016t
long-term results of, 1017
patient selection for, 2031
postoperative management, 1016
radionuclide evaluation of left ventricular function after, 842
residua of, 2030
right bundle branch block after, 1788, 1789
sequelae of, 2030
tetralogy of Fallot with, *1076,* 1076
persistent defect after repair, 1096, 2036
repair of, 1092-1093
transposition of the great arteries with, *1177,* 1177-1178
traumatic, 2537, 2538
tricuspid atresia with, 1119
Type I, 1003
Type II, 1003
Type III, 1003
Type IV, 1003
vasodilators for congestive heart failure in, 2093-2094, *2094*
ventricular inversion with, 1236-1237
hemodynamics and physiology of, 1241
with high pulmonary vascular resistance
clinical manifestations of, 1008
complications of repair of, 2263-2264
medical therapy for, 1015
Ventricular septum
anatomy of, 119, *120*
aneurysm of. *See* Aneurysm(s), ventricular
apical trabecular, 1003
echocardiographic assessment of, 773, *774*
in fetus, 810, *811-812*
formation of, 86-88, *89-91*
in atrioventricular canal defects, 1038
infundibular. *See* Ventricular septum, outlet
inlet, 1003
formation of, 86-87, *89*
membranous, 1003
outlet, 1003
formation of, 87-88, *90-91*
in double-outlet right ventricle, *1214,* 1214
perforation of
after myocardial infarction, 2283
regions of, 1003, *1004*
Swiss cheese, 1004
Ventricular tachycardia. *See also* Ventricular fibrillation
acute clinical situations associated with, 1881-1883
bidirectional, 1875, *1878*
in digitalis toxicity, *750,* 750
chronic
in infants, 1884-1885
differential diagnosis of, 1874-1875, 2546t
during pregnancy, 2382
electrocardiographic characteristics of, 1874-1876, *1875-1879*
electrophysiology studies of, 1749, 1879-1881, *1882-1883*
exercise-related, 1740, 1888
fetal, 1884
in otherwise normal heart, 1887-1888
in unoperated congenital heart disease, 1891-1892
in unoperated mitral valve prolapse, 1891
incessant, in infants
with myocardial tumor or hamartoma, 1640-1641, *1641,* 1653, 1884-1885, *1885-1887,* 2179-2181, *2180,* 2181t
management of
acute, 1897-1898
cardioversion in, 2171
chronic, 1898-1900
emergency, 2547t
surgical, 2179-2181, *2180*
with myocardial infarction, 1718
monomorphic
defined, 1881
noninvasive evaluation of, 1876-1879
nonsustained
defined, 1881
paroxysmal
in infants, 1884
polymorphic
defined, 1881
postoperative, 2258
preceding cardiac arrest
age and, 420-421
sudden death and, *1915,* 1915
supraventricular tachycardia vs., 1820, *1821*
sustained
defined, 1881
syncope due to, 1937, *1940*
torsades-de-pointes, 1875, *1879*
acute management of, 1897
in quinidine toxicity, 751, *752*
with myocardial infarction, 1715
management of, 1718
Ventricular trigeminy, 1872-1874, *1873*
Ventricular tumor(s)
tachycardia and syncope due to, 1937, *1940*
ventricular arrhythmias with, 1892, 1899-1900
in infants, 1640-1641, *1641,* 1653, 1884-1885, *1885-1887,* 2179-2181, *2180,* 2181t
Ventricular volume
as measure of preload, 232, *233*
calculation of, from cine-angiography, 496
Ventricular wall motion. *See* Wall motion
Ventricular wall stress. *See* Wall stress
Ventriculoarterial connection
echocardiographic assessment of, 771, *771-772, 779*
in fetus, 810, *813*
Ventriculoatrial shunt
for hydrocephalus
infections involving, 2463
Ventriculography. *See* Angiocardiography
Ventriculoinfundibular fold, 115-116, *116*
in double-outlet right ventricle, *1214,* 1214
Ventriculomyotomy. *See also* Myectomy
for hypertrophic cardiomyopathy
ventricular arrhythmias after, 1896
Ventriculoperitoneal shunt
for hydrocephalus
infections involving, 2463
Ventriculoradial dysplasia, 678t, 678
Ventriculotomy
right bundle branch block after, 1788
sequelae of, 2030
Verapamil, 2127t, 2133, 2551t
dosage adjustment for renal insufficiency, 2440t
drug interactions with, 2133
effects of
on abnormal automatic rhythms, 314
on electrocardiogram, 751
on pulmonary circulation, 374t, 378-379
for atrial flutter, 1857
for fetal tachycardia, 1908-1910
for hypertrophic cardiomyopathy, 1633
for myocardial protection, 271
for supraventricular tachycardia, 1822, 1825
for ventricular arrhythmias, 1899
for ventricular fibrillation, 1901
in cardiopulmonary resuscitation, 418
mechanism of action of, 305
pharmacokinetics of, 2133, 2364t
pharmacology of
in hepatic, gastrointestinal or nutritional disorders, 2366
problems with
in Wolff-Parkinson-White syndrome, 1914
side effects of, 2133
sinus node dysfunction and, 1775
use of, during pregnancy, 2385, 2386t
ventricular tachycardia and, 1897-1898
Vertebral artery(-ies)
formation of, 94
Vertical vein
anomalous
in partial anomalous pulmonary venous connection, 1149
in total anomalous pulmonary venous connection, 1154
Vertigo
syncope due to, 1940
Very-low-density lipoprotein. *See under* Lipoprotein(s)
Victorica and Gessner formula, 938, *939*
Vidarabine (adenine arabinoside), 2061

Vidicon tube(s), 555, 639
Vincristine
cardiotoxicity of, 2341
Virus(es). *See also* particular diseases
congenital infections with
cutaneous manifestations of, 2421
oncogenic, 30
Visceral situs. *See* Situs
Vistaril. *See* Hydroxyzine
Vital capacity, 353
Vitamin(s). *See also* particular vitamins
supplemental, 2354
Vitamin B_1. *See* Thiamine deficiency
Vitamin C
in iron chelation therapy, 2333
Vitamin D
supravalvular aortic stenosis and, 1343
Vitamin D-endocrine system, 463
Vitamin K
neonatal supplementation with, 2354
Vitelline vein(s), 98-99, *100*
V_{max}, 235, *236*
as contractility index, 225-226
VNTR (variable number of tandem repeat marker), 23
Voltage
activation, *296*, 296
defined, 2140
Voltage clamp experiment(s), 302
Volume of distribution
apparent, 469
Volume overload
blood pool imaging for assessment of, 842
chronic
effects on liver, 2359-2360
Von Recklinghausen disease. *See* Neurofibromatosis
Von Willebrand factor
endothelial synthesis of, 486
in pulmonary hypertension, 372
Von Willebrand's disease
mitral valve prolapse in, 2343
Voxel(s)
defined, 619, 630, 852
VP-16
cardiotoxicity of, 2341
Vulnerable period, 1871

Walker-Murdock sign, 2398
Wall motion
assessment of
by equilibrium blood pool imaging, 839
by first-pass blood pool imaging, 841
Wall stress, 232
afterload estimation from, 224
estimation of, 224, 251-252
increased
hypertrophy as compensation for, 252
instantaneous
afterload and, 235
internal cardiac work and, 251-252
myocardial oxygen consumption and, 252
compensatory effect of cardiac hypertrophy on, 246
Wandering pacemaker, 1954
Warfarin (Coumadin), 2080, 2553t
drug interactions with, 2080t
for pulmonary embolism, 2510
in idiopathic dilated cardiomyopathy management, 1624
in mitral prosthesis management, 1314
pharmacology of, 2364t
in hepatic, gastrointestinal or nutritional disorders, 2367
use of, during pregnancy, 2080, 2382
Warfarin embryopathy syndrome, 2382
Warming device(s)
for cardiac catheterization laboratory, 948-949
for neonate, 2481
Wasting, 2355
Water. *See also* Fluid(s)
excretion of
quantitation of, 456
renal transport of
regulation of, *2100*
Water loss
in neonate, 2482
Water-hammer pulse. *See under* Pulse
Watershed infarct(s)
due to cardiac surgery, 2313
Waterston-Cooley shunt, 2211
for single ventricle, 1268-1270
for tetralogy of Fallot, 1091-1092
sequelae of corrective surgery after, 2037-2038
for tricuspid atresia
drawbacks of, 1123, *1124*
nuclear magnetic resonance imaging of, 860
Watson, James, 4-5
Weight
birth
altitude and, 446
congenital heart disease and, 677
dosage schedules based on
multipliers for adult dose, 837t
nutritional status and, 2355
Weightlessness
birth, growth and development in, *438*, 438-439, 439t
effects of, 435-437, *436-437*, 437t
Wenckebach block. *See under* Atrioventricular block, second-degree
Werner's syndrome
atherosclerosis in, 1993
Wet lung syndrome. *See* Transient tachypnea of newborn
Wheezing
in myocardial infarction
management of, 1717
White, Paul Dudley, 1988, 1989
Wide QRS tachycardia
differential diagnosis of, 1820, *1821*
Wilcoxon method, 653
Williams syndrome, 980-981, 1344, 2407-2409, *2408*, 2430t
endocrine abnormalities in, 2498t
molecular basis of, 55
myocardial infarction in, 1712-1713
pulmonary artery stenosis in, 1409, *1412*
renal anomalies in, 2430t
supravalvular aortic stenosis and, 677t, 1343
Williams-Beuren syndrome. *See* Williams syndrome
Wilms' tumor, 988, *989*
involvement of great vessels or heart in, 2338, *2339*
Wilson, Frank
on faulty reading of electrocardiograms, 713
Wilson's central terminal, 504-506
Wilson's disease, 1674
Window-level setting, 630, *631*
Window-width setting, 630-631, *631*
Wobble hypothesis, 5-6
Wolff-Parkinson-White syndrome, 738-740, *739-740*
atrial fibrillation in, 1860-1861
atrial flutter in, 1853-1854
blood pool imaging in assessment of, 843
clinical applications of body surface mapping in, 519-520, *520*
concealed. *See* Kent bundle, concealed
digoxin use in, 1824, 1860-1861
electrocardiographic findings in
myocardial infarction vs., 1714
electrophysiologic studies in, *1748-1749*, 1749
exercise electrocardiography in assessment of, 1739
in Ebstein's anomaly, 1137, *1138*
inheritance patterns of, 55
intermittent, 1838
premature ventricular contractions vs., 1869
supraventricular tachycardia in, 1813, 1818t, 1834t, 1838, *1839*, 1839-1841
digoxin in management of, 1824
electrocardiographic characteristics of, 1835t, 1846t
electrophysiologic diagnosis of, 1830-1831, *1831-1832*, 1835t
inheritance pattern of, 55
sudden death and, *1914*, 1914
surgery for, 2174-2176, *2175-2178*, 2176t
treatment of, 1840-1841
ventricular tachycardia vs., 1881
syncope in, 1932, *1934-1935*
ventricular fibrillation in, 1900, 1901
Wolf-Hirschhorn syndrome, *184*, 184
Wolman disease, 1662
Wood unit(s), 932-933
Word processing program(s), 662
Work
cardiac
carbohydrate metabolism in response to, 194
lipid metabolism in response to, 195
myocardial oxygen consumption for, *251-252*, 251-253
of breathing, *355*, 355
Workers' Compensation, 2529

Xanthine oxidase
in free radical generation
in postischemic dysfunction, 275
Xenon
radionuclide-labeled
blood flow measurement using, 496
Xiphoid
hypersensitive, 1948
X-linked dominant inheritance, 174
X-linked recessive inheritance, 174
X-ray(s) (roentgen ray), 560
image creation by, 628
production of, 552, 553
X-ray beam
hardening of, 637-638
X-ray generator
for digital subtraction angiography system, 636
X-ray imaging system(s)
beam energy of, *629*, 629
image quality in, 628-630, *629-630*
X-ray tube(s), 553-554, *629*
for digital subtraction angiography system, 636

Yersinia enterocolitica infection
Lyme disease vs., 1538

Yersinia pseudotuberculosis infection
  Kawasaki disease and, 1549-1552
  Kawasaki disease vs., 1549

Z band(s), 130
Z filament(s), 212
Z line, 212
Zaroxolyn. *See* Metolazone
Zellweger syndrome, 2430t
Zero crossing circuit, 539
Zero-flow pressure, 256
Zeumatography
  rotating frame, 613
Zinacef. *See* Cefuroxime
Zofenopril
  pharmacology of
    in hepatic, gastrointestinal or nutritional disorders, 2367
